lieve it to be a completely satisfactory substitute for "flair," so far as we are concerned, in making straight prints, the best at the negative will yield by the straightforward exposure and velopment of bromide printing paper. I am also satisfied that it not only a rule which is near enough for ordinary practical work, t has an accuracy and precision far beyond ordinary requirements. If my letter is not already unbearably long, I may perhaps be lowed to tell two stories in substantiation of this claim. I had ade a set of prints from one negative. They were all developed ctorially to the same factor. On the following evening I wanted ore prints from the same negative of exactly the same depth. he same exposures (in point of time) were given, and development rried on to the same Watkins factor. All the prints made on the cond night proved to be of less depth. That meant that they ust have had less exposure. As the time of exposure was the me, then the light (electric) must have been of less intensity. pon further trial I found that 30 per cent. more exposure was quired on the second night compared with the first. I rang up e local power station, and they told me that my conclusion was rrect, for they were on that second night having trouble with a rnamo. The second story is similar. I was lecturing before a ub on factorial bromide work. I had my own negative, paper, veloper, and also my own electric exposing lamp. My exposure ad to be about 25 per cent. more (I am writing from memory) this club than at home. Upon inquiry, I found that their cur- nt was 210 volts and mine at home was 230 volts. On both occa- ons the result of factorial development was an accurate indication f the amount of exposure given. There is a precision about it hich is not possessed by any other ordinary photographic opera- on, and it is a power in our possession almost entirely neglected.—

ours faithfully,

B. T. J. GLOVER.

CAMERA FITTINGS.

To the Editors.

Gentlemen,—In your leader of September 2 on camera fittings, suggestion is made that adapters of brass should be fitted to mera by the optician, to enable a lens to be fitted on different meras. The idea is good, but these brass adapters are very avy; aluminium would be lighter, but metal adapters are expen- ive, and I think not so convenient as a method I have used for long time, by which any lens that is small can be used on any mera in the place.

I get some three-ply mahogany and cut it into panels, either ith a fine dovetail saw, or a sharp knife and a steel straight dge, to fit the various cameras. The largest lens panel is on the udio camera, so I make one to fit that, and fasten strips of wood n it to take, say, my 12 x 10 rectilinear lens, and a hole is bored ith an expanding bit to suit the lens. Four turn buttons are crewed on, two screwed up tight and two made movable to fasten he 12 x 10 lens board in. This lens board now becomes the tandard, and another panel is made to fit it of the three-ply wood. hole of suitable size is bored in it, and strips of wood glued and prigged on to fit a smaller lens board, which originally belonged o the half-plate field camera, but all the smaller lenses, even the 2 x 10 wide angle, are fitted on boards of this size, so that all he small lenses can be used on the half-plate field camera, whole- late studio camera, copying camera, or enlarger.

The copying camera is made to take the lens board of the 2 x 10 rectilinear, so are the enlarger and the whole-plate. By ing the adapting panel any of the smaller lenses can be used on ny of these cameras, also including the studio camera. One of hese adapter panels should be fitted to each camera, except the alf-plate outdoor one. They are easy to make and look quite eat if painted with "Nigrogene" or any other dead black. Of ourse, it is possible to manage with one adapter panel, but it is nnoying sometimes to find just when it is wanted badly for some ork in the studio that an assistant has got it with him on an utdoor job.

I think this is a better plan than heavy metal adapter flanges, hich involve screwing and unscrewing, which is a nuisance, especially for outdoor work. If neither the photographer nor his assistants are handy men (but very few are not), the local cabinet-maker would make them—I was going to say at a trifling cost, but in these days when the British working man expects to get three times his pre-war wages and does less than a third of his pre-war work, we don't get anything at a trifling cost. So I find it comes cheaper to do all the odd carpentering jobs myself that I can, and being a bit of a "messer," as the "competent domestic authority" calls me, I rather enjoy doing it.

I had some difficulty in getting a cheap expanding bit, but found that a washer-cutter answered just as well. I was told by the man who sold it me that in some places it is known as a "wimble."

—Yours truly.

BIFOCAL.

EARLY PHOTOGRAPHY BY MAGNESIUM LIGHT.

To the Editors.

Gentlemen,—In the "British Journal of Photography" of August 19, 1921, p. 497, Mr. E. J. Wall criticises my "Geschichte der Photographie" (History of Photography). In doing so, however, he quotes from the latter only a fragment of the treatment accorded to photography by megnesium light, and removes from its context that portion which related to Gaedicke and Miethe. In this way the wrong impression is created that I did not record the priority of the discovery of an explosive flash powder by J. Traill Taylor in 1865. This, however, is not the case, for I wrote ("Geschichte der Photographie," 1905, p. 330): "The first data for the production of a quick-burning mixture containing magnesium powder were given by Traill Taylor in the year 1865 (mixture of potassium chlorate, sulphur and antimony sulphide). These experiments, however, did not lead to any practical use in portrait photography on account of the small sensitiveness of the wet collodion plate and the high cost of magnesum. An attempt by Larkin to burn magnesium in a lamp proved unsuccessful. The next attempt to employ mixtures containing magnesium powder and pure potassium chlorate were made by Kenyon in 1883. . . . Photography with magnesium powder in the form of flashlight was first brought to a successful issue by Gaedicke and Miethe in Berlin in 1887. . . . Shortly after the Gaedicke-Miethe flash powder became known Armstrong showed that pure magnesium powder when blown through a flame gave an intense light."

What other account would Mr. Wall have? I set forth the work of Taylor, Larkin and Kenyon in correct historical sequence, and then the patents and publications by Gaedicke and Miethe in 1887. I *did not say* that Gaedicke and Miethe were the first to have employed an explosive magnesium flash powder, as Mr. Wall represents me to have done on page 497 of the "British Journal."

It is chronologically correct to say that the discovery made by Taylor was afterwards made successful by Gaedicke and Miethe, since during the interval the electro-chemical production of magnesium had greatly reduced the price, and the dry plate had come into use, so that Gaedicke and Miethe arrived at the appropriate moment and provided a successful impulse to this branch of work.

Historically my account is correct. But it is incorrect, as Mr. Walls seeks to persuade the readers of the "British Journal," that I described the Gaedicke-Miethe flash powder patent as "epochmachend." Mr. Wall is profuse in hie use of italics for the purpose of giving prominence to something which I have never written.

"Thus is history made," says Mr. Wall, in reference to my historical work on this matter. He writes this, whilst suppressing the first part of what I have written and whilst giving an account of the middle part (relating to Miethe and Gaedicke) in a manner to distort the sense. Finally, he incorrectly puts in the phrase "epochmachenden," and thereby destroys the objective character of the historical treatment in the minds of less informed readers, whereas this character was most fully and carefully preserved in my account of the history of the magnesium light.

I shall be very much obliged if you will publish this reply to Mr. E. J. Wall.—Yours faithfully,

J. M. EDER.

Vienna, September 8.

Answers to Correspondents.

In accordance with our present practice a relatively small space is allotted in each issue to replies to correspondents.

We will answer by post if stamped and addressed envelope is enclosed for reply, 5-cent International Coupon, from readers abroad

Queries to be answered in the Friday's "Journal" must reach us not later than Tuesday (posted Monday), and should be addressed to the Editors.

H. C.—We suppose you are using the customary method of dipping the prints in alcohol and hot rolling. The only alternative to this which we know is the use of a cement made by Messrs. Rheinlander and Son, Rodney Road, New Maldon, Surrey.

F. A.—You should apply to the Registrar of Trade Marks and Names, 25, Southampton Buildings, London, W.C.2, for circular of instructions for application for a trade mark. We believe, as a rule, that a month or two elapses between the time of applying for a mark and its placing on the Register.

A. A.—We think you are not using enough paramidophenol in proportion to the carbonate, and also are using too much bromide. The formula in the "Almanac" would give good results, providing that the paramidophenol-hydrochloride is of reasonable quality. We are sorry that we cannot undertake to test developing materials, and have returned your sample.

G. C.—We think the markings are fixing stains, that is to say due to partly soluble emulsion, which has been left in the prints. We advise using a fixing bath of 1½ lbs. of hypo in 80 ozs. of water, and preferably passing prints through two fixing baths, No. 2 being kept reasonably fresh and replacing No. 1 as soon as a considerable number of prints have been passed through it.

E. H. N. W.—The Kodak amidol formula for bromide paper is:—

Sodium sulphite, cryst.	1 oz.
Water	20 ozs.
Amidol	60 grs.
Potass. bromide, 10 per cent. solution.	20 drops.

The amidol is dissolved immediately before the developer is to be used.

D. D.—All the swing taps that we have used begin to leak fairly soon when used on the ordinary main water pressure. The only way out of the difficulty is to have a tank fitted up a few feet above the dark-room sink and to connect the swing tap with that, getting the plumber to provide the tank with a ball valve, which keeps it constantly full and prevents overflow, as is done in the ordinary tanks placed on the top floor in a house.

E. D.—About the best stain remover for xylonite dishes is a solution of permanganate of potash, say 10 grs. or 20 grs. in a pint of water, with, say, 1 oz. of strong sulphuric acid added. This will clear off almost any stain, but is liable to leave a brown deposit from the permanganate. In the case of earthenware dishes this can be cleared off by a little bisulphite of soda, but we would not say that that could be done in the case of xylonite. At any rate, the permanganate will make the dish chemically clean for photographic use.

E. L. W.—Answering your specific questions, the camera would be quite suitable for groups out of doors or in the studio. It is a bad camera for copying owing to its short extension. The lens is a slow one, one-quarter the speed of the ordinary portrait lens. It is not a very good lens for Autochrome work, since for this latter a better degree of correction is advisable than was obtained with these old rapid rectilinear lenses; and also the general experience is that the best Autochromes are made with an aperture not smaller than *f*/6.

C. D. V.—(1) We have no doubt acetylene could be used for heating a dry-mounting press, but the burner would have to be specially designed and made, and we should think it would not be the easiest matter to keep the press at a uniform temperature. As regards the burner, you could not do better than write to Mr. R. J. Moss, 98, Snow Hill, Birmingham, stating your requirements. (2) You can reduce the intensified negative with Farmer's reducer. (3) Metol-hydroquinone, owing to its containing alkali and sometimes caustic soda, is much more likely to produce frilling. You had better stick to amidol.

J. LADE.—(1) An oven is not hot enough. You should heat t damp chloride in an old iron saucepan over the fire. If y keep the dry chloride in a biscuit tin with a well-fitting lid, will keep dry for a reasonable time; for much longer if you se the lid with a band of surgical plaster. (2) We do not think is, but try Tanner and Co., Ltd., Dorset Street, Salisbury Squar London, E.C.4. (3) For good drawing, we would prefer a co siderably longer focus, say 10 to 12 inches. (4) The plan reducing the contrast simply by bleaching the negative in sol tion of mercury bichloride is a very old one. It is of considerab benefit to negatives which are of very harsh contrast.

A. B.—There is no disadvantage in having the lens of a refle camera in a focussing mount, and it does in fact provide add tional extension to the amount of an inch or two. Of course, i buying a new lens for a reflex of anything like decent extensio it is an altogether unnecessary expense. Using the most rapi plates and *f*/4.5 aperture, we should think you might give a exposure of about half a second in the studio. If really goo rendering of gradation is to be obtained, we do not think the is much to be said for the suggestion of making snap exposur of the sitter of whom a bust or three-quarter length portrait being taken.

J M. DUNN.—Brightness of illumination and safety for a give kind of material are opposite qualities, and, therefore, th making of a light to secure both is always a matter of com promise. Mr. Howard Farmer, who introduced the bichromat lamp, used to add a little eosine (red dye) to the solution i order to make the light safer, but although we have not tried it we should think that the eosine is oxidised in course of tim by the bichromate. In making up solutions with dyes only the most suitable dyes for the purpose are tartrazine (or brillian yellow or naphthol yellow or auramine) for yellow light; tartra bine and rose bengal for red light, with addition of methyl viole for orthochromatic plates.

CAMERA AS LUGGAGE.—While travelling on the G.W.R. last week with a 8½ × 6½ camera and tripod, the ticket collector demanded excess fare, on the grounds that a camera was not personal luggage; I refused to pay, and he then took my name and address, and said the company would make me pay. Do you know if a railway company can make a photographer pay for his apparatus? I have carried a camera for a great many years, and this is the first time that I have been asked to do so. It was not an excursion train, and my total baggage, including camera, was about 40 lbs.—H. K.

There is the authority of the Ministry of Transport that the charge for a camera as non-personal luggage is contrary to the railway regulations. We referred to an actual case of the same kind in our issues of April 30 and June 11, 1920.

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 3203. Vol. LXVIII. FRIDAY, SEPTEMBER 23, 1921. Price Fourpence.

Contents.

SUMMARY.

The exhibition of the Royal Photographic Society opened on Monday last at 35, Russell Square, and remains open until October 29. Mr. F. C. Tilney contributes a preliminary review of the pictorial section. (P. 563). The most notable exhibit in the technical section is the example of the stereo-photo-synthesis of M. Louis Lumière in the shape of a portrait of the Postmaster-General. (P. 564.)

The exhibition contains some remarkably fine examples of the Autochrome process by Mr. Henry Irving (p. 565), and, in addition to a fine collection of prints by manufacturers, has a further exhibit of interest, namely, the cameras employed by Fox Talbot in his pioneer experiments. (P. 565.)

Mr. Pirie Macdonald, the New York "photographer of men," at present on a visit to England, was entertained to dinner last week by the Professional Photographers' Association, and delivered an eloquent address, of which the running sentiment was a plea for a closer personal knowledge of each other by American and British photographers. Mr. Macdonald said a little on the mental attitude of his own, to which he attributed any merits which his portraits might possess. (P. 566.)

Mr. Macdonald referred, in the course of a subsequent informal talk, to the system of community advertising, which had had beneficial effects in centres of population containing a number of photographers. (P. 561.)

In the concluding portion of his review of the London Salon, now open at 5a, Pall Mall East, Mr. Tilney deals chiefly with portraits of children and with aspects of the landscape photographs. (P. 569.)

In a leading article we draw attention to the practical objections to an ideal system of projection for the purposes of enlargement of negatives. Partial or almost complete diffusion of light is greatly preferable in practice to the use of a point source of light. We deal with the forms which the practical systems may advantageously take. (P. 562.)

The recently passed Safeguarding of Industries Act imposes a duty of 33⅓ per cent. on certain photographic goods entering this country. The chief of these goods are lenses and cameras, optical lanterns and cinematographs, and photographic developers. (P. 562.)

Mr. T. C. Turner defends himself against critics of his photography of the disaster to the R.38 airship. (P. 572.)

Particulars of courses of instruction in photography within the London area will be found on pp. 571-572.

A bogus canvasser for photographic enlargements was sentenced to two years' imprisonment last week. (P. 571.)

Further correspondence on the respective merits of plates and film will be found on pp. 574-575.

Failure to mix the developing solution thoroughly in its tank is responsible for some of the irregular markings found to occur when using this system of development. (P. 562.)

EX CATHEDRA.

Pirie Macdonald. The eloquent address delivered by Mr. Pirie Macdonald at the dinner arranged in his honour last week by the Professional Photographers' Association represents only a small part of the many things which the distinguished New York "photographer of men" said on the occasion. The formalities of the toast and its reply having been disposed of, a most enjoyable hour or two were passed in conversation on topics of professional photographic portraiture which have a common interest for photographers on both sides of the Atlantic. You cannot listen to Mr. Macdonald for very long without coming under the spell of his personality. As will be seen from his address on another page, he himself has a very simple formula for his philosophy of life. Herein we think he is mistaken; if his formula of seeking to discover some reason or other for liking a man represented his attitude to life in the degree which he asked us to believe it did, he would be very different from the strong, human, complex character that he is. It requires a good deal more than the expressed amiable desire to be blind to people's failings to account for the big broad personality of Mr. Macdonald or his great and healthy influence upon photographers in his own country. We could do with more men of his calibre here, and it is to be hoped that it may be possible for him to take part in a future Congress of the Professional Photographers' Association.

* * *

Community Advertising. One of the topics on which Mr. Macdonald touched in his post-prandial talk was the system which has been adopted with great success by photographers in many of the large centres of population in the United States for approaching the public, on a co-operative basis, with offers of photographic portraiture. In many towns, during the month or two before Christmas, the photographers in a town have joined together in discontinuing their individual advertising in the newspapers and in replacing it by a series of announcements advertising, not themselves collectively, but photographic portraits pure and simple. In the case of some, the individual cost will be a little greater than on the individual system; in the case of others, a little less. And as regards the returns, it has been definitely found that the business brought to the studios by thus pooling the advertising effort has been greater than that when photographers were advertising in competition. In this country we have had occasionally communal efforts of this kind, for example, in regard to closing of the studios in a town for the same period of a summer holiday; and, spurred by the incursions of free sitting firms, Edinburgh photographers, not long ago, united in a similar manner for the purpose of warning the public. But in its application to the everyday purpose of bringing sitters to the

studios, the system, so far as we know, has not been given the opportunity of proving its success on the scale which has been accorded to it in the United States.

* * *

Mixing Tank Developer. Those photographers who practise tank development and employ one of the single-solution concentrated developing agents used very dilute, should make quite sure that the solution is thoroughly mixed before pouring it into the tank, for if this point has not been attended to curious irregular patches of unequal density may appear upon the negatives. Recently, we were shown a negative suffering from this defect, which is very like that produced through failure to agitate the solution in one of the vertical tanks. The worker had in this case moved the tank several times during the time development was in progress. What actually caused the marking in question was the fact that the developer had been mixed some time beforehand in a large jug and poured directly into the tank. Being imperfectly mixed, the agent got to work at some parts of the plate more quickly than at others. The harm had in this case been done in the initial stages of development. Tank development is one of those operations that demands every care if the results are to be free from defects, and though an improperly-mixed developer may do its work satisfactorily nine times out of ten, the tenth time it may happen to spoil an irreplaceable negative.

* * *

Duties on Photographic Imports. From October 1 next certain photographic goods coming into this country from countries overseas, which are not part of the British Empire, will be subject to the payment of a duty equal to one-third of the value of the goods. This provision is authorised by the Safeguarding of Industries Act, which, after much debate and revision in the House of Commons, received the Royal Assent during August last. The schedule of the Act specifies certain classes of goods to which the provision of the Act shall apply, and the Board of Trade, at the end of last week, issued a 73-page list of particular articles which are defined by the Board as falling within the respective classes to which the Act applies. In class A (optical glass and optical elements) unmounted photographic and projection lenses are included, also unmounted condenser lenses and optical light-filters. In class B (optical instruments), photographic cameras, with or without lenses, finders, optical lanterns and cinematographs, stereoscopes, and photo-micrographic apparatus are included; also mounted photographic lenses and condensers. The chief part of the list, however, is occupied by the names of chemical substances, subject to the 33 1-3 per cent. duty, in consequence of their being synthetic organic chemicals or chemical substances of special purity as required, for example, in analysis. Inasmuch as the commonly used developers, such as amidol, glycin, hydroquinone, metol, paramidophenol, and pyrogallic acid come within one or other of these definitions, they are subject to the duty. The Act is put forward as a measure for the safeguarding of certain special industries against the effects of the current depreciation of foreign currencies, and it is provided that it shall continue in force for a period limited to five years. Part I. of the Act, which deals with the imposition of the 33 1-3 duty on goods of the classes set forth in the schedule, does not, however, discriminate between countries the currency of which is depreciated in reference to that of Great Britain and those the currency of which is not depreciated. At any rate, we can see nothing in this part of the Act in the nature of such discrimination. Plainly the duty will apply to goods imported from the United States equally to those from countries such as France and Germany, in which currency is greatly depreciated. The value of any imported goods for the purposes of the Act is taken as the price which an importer would give for the goods if the goods were delivered to him, freight and insurance paid, at the port of importation, and duty is to be paid on that value as fixed by the Commissioners.

ILLUMINANTS IN ENLARGING.

Most writers upon the subject of projected images have assumed that the optical system of the lantern is practically perfect and that the source of light approaches the theoretical point. This is far from the case in practice, and consequently it is generally necessary to overlook theory and to make the best of the condensers, lenses and lights as they are usually found. The production of an optically perfect condenser of, say, 8½ in. in diameter would be such a costly process that few people could afford to purchase it, and consequently it becomes necessary to make the best of such as can be procured at a reasonable price. Fortunately the fact that rather larger sources of light than the electric arc are available makes the task rather simpler than it would otherwise be. The electric arc, which from its small area would appear to be an ideal illuminant for enlarging, is perhaps the most difficult to handle in practice, the chief difficulty being the erratic burning of the arcs in most automatic lamps. In these the carbons are necessarily in line, and the slightest variation in the composition of these causes the arc to shift in a most aggravating manner. It has been found in actual practice that the effective exposure may be halved or doubled as the case may be when making two exposures from the same negative in quick succession, this being due to the fact that at one time the arc is burning on the side nearest the condensers, while a few moments later it has veered round to the farther side or vice versa. The only arc free from this objection is that obtained by placing the carbons at right angles, but as this can only be obtained with a hand feed it is not so convenient for enlarging where there are more distractions than in lantern-slide projection. The lamps used in cinematograph projectors are steady in burning by reason of the shortness of the arc and the large size of the carbons, but these, too, need constant attention, and may be dismissed as unsuitable for photographic work.

It is therefore necessary to fall back upon less powerful sources of illumination, such as the incandescent electric light, acetylene, and incandescent gas. Good work has been done with ordinary petroleum lamps in the past, but few of these are now in use. The incandescent electric lamp, and particularly the gas-filled or half-watt type, is probably the best form of illuminant where electric current is available. The most suitable form of lamp is one in which the metallic filament is compressed within a small area, such lamps being made for motor-car lights that are usually for low voltages only and cannot be used upon circuits of 100 to 240 volts. There is a hope that they will shortly be obtainable for higher voltages. The ordinary small half-watt lamps, in spite of their widely-spread filaments, are, however, quite suitable if the point of light idea is discarded and a finely-ground glass diffuser placed as near the bulb as is possible. This diffuser should be no larger than is necessary to cover the filament, as by reducing the area the risk of fracture by uneven heating is minimised. A frosted globe would be even more convenient, but as clear globes are more easily

obtained, the independent diffuser is, upon the whole, to be preferred. The object of the diffuser is, of course, to prevent the projection of a more or less sharply-defined image of the filament upon the focussing board. It has been a common practice to interpose a ground-glass screen between the light and condenser, or even to place it between the lenses of the condenser, but the nearer it is to the light the less loss of illumination occurs.

The incandescent gas mantle is next in merit to the electric light, and will be found amply sufficient for all but the greatest magnifications. Here, again, the ground-glass diffuser is necessary to prevent the texture of the mantle from showing. The inverted form is preferable to the upright, but the latter will answer well if a diaphragm with a diameter of about 1¼ in. is placed close up, so as to cut out the upper and lower portions. This greatly improves the definition.

Acetylene is a satisfactory illuminant and, as a rule, can be used without a diffuser. The dark room should, however, be well ventilated, as the fumes are apt to cause headache and nausea in a confined space.

The effect upon the functioning of the lens diaphragm which results from variation of the size of the illuminant must not be overlooked. If a very small source of light, such as an arc burning carbons less than a quarter of an inch in diameter, be used, the lens may be stopped down to quite a small aperture without there being an appreciable difference between this and the full opening of the lens; but if a diffuser be interposed, the effect of reduction of aperture is at once perceptible. The conditions are the same if a large unscreened light, such as the incandescent mantle or an acetylene or oil flame, be used.

In some modern enlargers a rising and falling front, similar to that of a camera, has been fitted, the idea being to facilitate adjusting the image upon the screen. This is totally wrong in principle, as the centres of the light, condenser and lens should always be in a straight line. If the light be out of position, an improvement in illumination may be obtained by moving the front, but the proper course is to adjust the light and leave the optical system undisturbed.

Enlargements of very fine quality may be obtained without using a condenser, but at the expense of much longer exposures. Three methods are generally employed, the most effective being the illumination of the negative by a gridiron pattern of mercury-vapour lamp placed behind a sheet of ground glass. Another is the use of a large facetted reflector having an ordinary metallic filament lamp in the centre, a diffusing screen being interposed between this and the negative. The third and most usual in this country is the use of a powerfully-illuminated white screen, which reflects light from screened lamps through the negative. The exposures by this system were usually too long for commercial use, but the introduction of the half-watt lamp has made a great difference in this respect.

THE ROYAL PHOTOGRAPHIC SOCIETY'S EXHIBITION.

The sixty-sixth exhibition of the Royal Photographic Society opened on Monday last at the Society's house, 35, Russell Square, where it remains open daily from 11 a.m. to 9 p.m. until October 29. As was the case last year, the pictorial section, which is accommodated in the Society's lecture hall, is illuminated entirely by artificial light. The natural lighting of the room is very unfavourable for the viewing of pictures, and though one could wish to dispense with artificial light for the showing of a collection of photographs, at any rate the Society is fortunate that its exhibition was not held during the recent hot summer, for had this been the case a visit to it would have been a somewhat trying experience. During the present cool weather, there is nothing to complain of in the temperature or ventilation of the gallery.

Mr. Tilney, in the article which appears below, reviews the pictorial section, which, again, is hung entirely under glass provided by the Society, and strikes a note of brightness and lightness by the preponderance of light mounts.

The technical and colour photography sections are by no means up to the standard of recent years. We refer below to the very interesting exhibit, in the former, of the relief effect portrait by M. Louis Lumière, which is the chief exhibit of novelty in the technical section.

In the rear library, on the ground floor, is an exceedingly fine collection of X-ray negatives made on Eastman Duplitized film, and confined particularly to radiographs of the stomach and teeth. This collection has been arranged by Mr. N. E. Luboshey, who at intervals during the exhibition is giving demonstrations of radiography with an exceedingly simple and compact outfit of the Thomson-Houston Company, fitted with one of the small Coolidge tubes. The degree to which the technique of making X-ray exposures has been simplified by the use of an outfit of this kind is particularly worthy of attention.

Lectures are given on the Tuesday and Friday evenings of each week during the period of the exhibition. To-night, September 23, Mr. James Shaw, of Manchester, will lecture on "Picturesque Cities of France." On Tuesday next Capt. C. W. R. Knight, M.C., will recount "Further Adventures among the Tree Tops," and on Friday, to-morrow week, the lecturer is Mr. J. Dudley Johnston, and his subject, "Wonderlands of the Western World." All these are lantern lectures, and are held at 8 p.m. Visitors should, therefore, note that it is not possible to examine the pictorial collection after this hour on these evenings, since the exhibits are arranged in the lecture hall.

THE PICTORIAL SECTION.

Reluctant as one must be to cry over spilt milk, it is almost impossible to avoid an expressed regret that so good a show as there is in Russell Square could not have been housed in a gallery built for exhibition purposes. The room is spacious and noble, but its unfitteelness for a display of pictures is a serious bar to their due appreciation. The plan of last year is still followed, namely the shutting out of daylight and the illumination by electric lamps. But to come out of the broad light of day into these nocturnal conditions is to experience a visual groping for the first half-hour until one's eyes have settled down to make the best of a bad job. Even then the reflections in the glasses from the bright ceiling and frieze is a constant embarrassment. The finer nuances of tone are sacrificed, and the works lose the delicacy and relative values they actually possess. Surely some daylight would be better than none. Making allowance for these drawbacks the impression is that of a very worthy exhibition; not surpassing that of last year, but perhaps no less good. The landscapes are in the majority, and number some unusually fine examples from the faithful Fellows and members who, to their credit be it said, stand staunchly by Alma Mater.

Of the portraits there are, perhaps, half a dozen excellent

things almost all within the first page of the catalogue. Some leading professional photographers are chiefly responsible for these. Mr. W. Thomas, who sends a duplicate of "The Lord Chief Justice of England" (10), which figures at the Salon; Mr. Herbert Lambert, who shows another version of the little girl whom here he calls "Tousel Head" (69), and presents as a half-length nude; and his "Mary" (77), another little girl standing at profile and treated in an oval. This is a print of much charm, and perhaps his best in this collection. Mr. C. Pollard Crowther likewise sends a variation of a Salon subject, "In Latitude 15.S." (149), a rather less horrific villain than the Grand Guignol gentleman at Pall Mall.

One of the most taking portraits is "Mrs. M. W." (2), by E. Drummond Young. The subject is half the victory here, but happy lines and masses of fascinating textures in the costume complete a most pleasing result. A very forceful head comes from Horace Jackson, who calls it "Out of the Blackness" (3), which, indeed, it is. Only half the lady's face has come out; all the rest is blackness, which, however, makes an effective pattern in the design. Mrs. Maud Basil's best work is "Ferdinand Flodin, of Stockholm" (4), a most spontaneous looking portrait at full face and about life-size. Another work of strong effect is Edward Weston's "Head of an Italian Girl" (9). This is most forcefully modelled and posed so that a very dramatic effect is derived from the part of an uplifted arm, which the close trimming allows to be seen.

N. E. Luboshey has also duplicated a Salon print, which there appears as "Nikola Persheid," and here as "Nicola Perschiede, Esq." (61), an unfair trap for the critic. His portrait of the president, "G. H. Rodman, Esq., M.D." (64), though a good likeness and well posed, is quite unnecessarily dark—not the dark of legitimate shade, but the swarthiness of a leathery brown skin, which is not true to the sitter. Miss Alice Boughton is to be commended for resisting the temptation of making something sensational of "Gilbert K. Chesterton, Esq." (113), who is usually regarded as a lion who should be made to perform in public.

Other outstanding works come within the classification of figure subjects. One such is Louis Fleckenstein's "Cave Woman" (162), a head and shoulders in sunlight, having dense shadows proper to the absence of reflected light from the cave at the entrance of which she appears to stand. There is undoubtedly something primeval about this head which justifies the title. Another is Mrs. Ralli's "Umbrella Maker" (160), probably umbrella mender is intended. He is an old perambulating jobber sitting in the blazing sun against a bright wall in Mrs. Ralli's usual manner for a strong effect. Dr. Geo. H. Rodman's portrait of "Herbert Lambert, Esq." (68), is quiet and accomplished, although the sitter seems to be gripping a lens without any photographic purpose. In "Geo. Eastman, Esq." (65), Mr. Luboshey also adopts the quiet and restrained style. It is distinguished, although it has not the richness of tone that Nicola Perscheid possesses.

For landscape and street scenes the exhibition is, on the whole, more noteworthy than for figure work. There is a capital bromoil print by Joseph Petrocelli, whose name is new to me. Its title is "The Curb Market, New York City" (52), and its subject is a narrow street between tall houses, and crowded with people. The pavement is flooded with rain, umbrellas are up, mist is in the air, and a dim light drops down from the sky which seems far away above the narrow gorge of buildings. Of its kind there is little to beat it in the show. Beautiful quality, and an imposing and simple design characterise Hector Murchison's "Southwark Bridge in the Remaking" (51). The same merits are shown by Thos. H. B. Scott in "Evening: Chichester" (55), where a corner of the cathedral is selected to make a noble design. Quite different material is utilised by Arthur C. Banfield, who finds inspiration in the ultra commonplace of wooden erections and brick shafts for his "Generating Station" (152), but by virtue of good composition, simple tonality and exquisite gradation has produced a thing of much poetry.

Pure out-of-door countryside feeling is seen in one or two works by Bertram Cox, of which it is difficult to say which is best. Fred Judge sends two transfer prints, in his inimitable style, that of "Newcastle" (92) being remarkable for fine breadth of effect and luminosity in the sky. Thomas Bell shows the poetry of the Thames in his "London" (100), a capitally composed view, with dark piles in the foreground, and St. Magnus tower beyond. A good picture has also been made out of smoke and turmoil by George F. Prior, in "Ship Repairs, Ramsgate Harbour" (146). Further prints well worthy of notice will be dealt with in another article.

There is, of course, a large proportion of American work, but it does not seem to preponderate, as it did last year, and that is something to the credit of British workers who, after all, should make the exhibition of the Royal Photographic Society of Great Britain a show of British work primarily.

F. C. Tilney.

SCIENTIFIC AND TECHNICAL SECTION.

Both in the number and the interest of the exhibits this section shows a distinct falling off compared with the last year or two; and these latter were far below those of the palmy days of the Society's exhibitions in the New Gallery. Apparently the war has had the effect of disturbing the lines of communication between the Society and many of those in overseas countries who were notable contributors to the scientific section in pre-war days. Re-establishment takes time, but it is evident that a good deal of spade work requires to be done in order to bring every autumn to the house of the Society examples of the varied work in scientific investigation, manufacture, exploration, process work and printing (to name only a few departments of work) which *is* being done by photographic methods.

The exhibit of chief interest in the technical section is an example (367) of the photographic method of reproducing objects with the illusion of natural form or relief, devised by M. Louis Lumière. A note in the catalogue describes the practical means adopted in the process, and usefully supplements the scientific exposition by M. Lumière, which we translated into these pages a few months ago. M. Lumière's example of a "solid object" is the Postmaster-General, Mr. F. G. Kellaway, M.P. The many members of the public who pay double and triple postal rates for a service of efficiency in inverse proportion may, perhaps, be excused if they look without enthusiasm upon this realistic portrait of the Postmaster-General. However, from some mistaken notion, the exhibit, which consists of several positive transparencies, one behind another, illuminated by transmitted light, has been boxed in a brown-paper structure, so that it cannot be viewed at a nearer distance than 40 or 50 inches. As it is evident that in taking the photographs M. Lumière employed a focal length of lens very much less than this distance, the relief in the portrait, as seen from the enforced distance, is enormously reduced. Although it is necessary that the observer should take up a correct position in viewing the transparencies, we think it would be better to remove the brown-paper enclosure, or at any rate shorten it, to allow of viewing from a very much closer standpoint. The exhibit is an exceedingly interesting one, and under correct viewing the appearance of relief and solidity is extremely striking.

Next in interest are the photographs of natural history subjects made with the aid of flashlight by O. J. Wilkinson. The subjects (253—255) include spiders, butterflies, and moths, one series recording the pupation of the Painted Lady butterfly. When it is mentioned that most of the subjects are photographed on a unit scale of reproduction, and with a lens working at *f*/32, it will be understood that Mr. Wilkinson has certainly explored with very great success a new technical branch of nature photography. Almost without exception his

prints are photographically excellent in every way. He receives a medal.

Hugh Main, B.Sc., contributes some examples of his always interesting studies of insects and reptiles (258—261). He and F. Martin Duncan, F.R.M.S., are almost the only two exhibitors of work which comes within the so-called category of "Nature photography."

Radiography is represented by some fine work, among which must be mentioned the radiographs of the thorax (268 and 270) made at King's College, and shown by N. E. Luboshey. The location of disease and mechanical treatment in teeth by means of radiographs, is well illustrated in Nos. 271 to 275 by J. King, of Paris. Among the industrial applications of X-ray photography a remarkable example is the pair of prints (279—280) by the Sunic Research Laboratories, showing the great difference between genuine and imitation Wedgwood ware.

In photo-micrography the work of outstanding merit is that of John H. Pledge, F.R.M.S., a series of photo-micrographs (293—301) at thirty magnifications, of the pedipalps of spiders. E. H. Ellis contributes a good series illustrating the germination of orchid seeds (310).

In astronomical and meteorological photography the chief exhibits are those of sun spots, by the Astronomer Royal (313—358), and the cloud studies of G. A. Clarke (296). The pair of prints of a water-spout in the Black Sea (293—294) are interesting records of this phenomenon.

In a glass case are some small specimens (364—366) of the photo-sculpture process of Howard M. Edmonds, of which some details were recently given in the "Amateur Photographer." Apparently Mr. Edmonds photographs the sitter whilst at the same time obliquely projecting upon the face a transparency consisting of an extremely fine spiral curve. The different directions assumed by the images of the lines, according to the inclination of the particular part of the face to the axis of the projection system is employed in some way as a guide in drilling out the material of the relief with a fine high-speed drill. It would seem that the mechanical appliances required (which we are informed weigh more than a ton) are somewhat out of proportion to the quality and size of the two small examples which are shown. However, Mr. Edmonds is to lecture before the Society during the month of December on his process, so that there will be the opportunity of learning more about it.

COLOUR PHOTOGRAPHY.

Among the colour transparencies by the Autochrome and Paget processes, those by Henry Irving exhibit a perfection of technique miles ahead of any others. We say this even though the collection includes Autochromes by such accomplished workers as Miss Helen Messinger Murdoch, Walter Stoneman, and Louis J. Steele. The exhibition is deserving of a visit if only to see and admire Mr. Irving's work, which is characterised by a most beautiful rendering of colour in lights and shadows and by a remarkable transparency. The medal is awarded to "Apples" (414), but it is difficult to draw comparisons between this piece of work and others, in particular "Rosebuds Opening" (419), "Flowers in the Corn" (434), "Flowers and Gorse" (448), and "Sycamore Fruits" (449), all by the same worker. The judges must have felt themselves on the horns of a dilemma in selecting one or other of these for the distinction of a medal.

Louis J. Steele's work is, perhaps, not quite as high in quality as in previous years. A medal goes to his "Chewing the Cud" (445), a clever impressionistic study of recumbent cows in a sunlit orchard. Miss Murdoch's large Autochromes illustrate her travels, and include studies of "Natives at the Zoo, Rangoon" (394), "The Palace of Taj Mahal, Agra" (405), "Nile Boats, Luxor" (424), and "Elephants Bathing, Ceylon" (427). All these are transparencies of a very high degree of technique. Mr. Stoneman's work ranges from woodlands and gardens to portraiture, and includes a fine study (438) of a woman, whose vivd red-brown hair makes a clash of colour with the spotty pattern of a sunshade.

Next to the work of these exhibitors, the Autochrome of chief interest is "With Apologies to Sir William Orpen" (400), by N. E. Luboshey, a clever skit on the famous painting at the last Academy. Mr. Luboshey describes it as a "combination Autochrome," which apparently means that, in accordance with his inevitable tendency to wizardry in photographic manipulation, he has registered a black-and-white positive against the Autochrome image.

There are only a few examples of the Paget process in the collection, but these are very good. They are chiefly by W. E. Unwin, whose "Dancers" (396) is a pretty trifle. The reproductions of pictures by Chinese artists painted on rice paper (403 and 404) are also excellent. A variety of the Paget process is represented by the clever instantaneous colour photographs of stage scenes by T. J. Offer, who, it will be remembered, described his process in the "Colour Photography Supplement" about a year ago. He shows the results obtained in this way from "Afgar," "Chu Chin Chow," and other performances (409, 422, and 450). A somewhat mediocre Autochrome (406) by W. Smoker is described in the catalogue by a curious footnote to the effect that "light reflected from a tarred shed appears as a glass conservatory." We have tried in vain to imagine what light looks like when impersonating a glass conservatory. If we could imagine it, it would give credence to the police-court story (from Penge) a few years ago, according to which a burglar escaped detection by impersonating a small dustbin!

In writing of the colour transparencies, it seems pertinent to ask whether in future exhibitions these transparencies cannot be shown more satisfactorily. The method at present adopted, of illuminating them from above and viewing their reflections in a mirror, is not bad so far as illumination is concerned, but has the distressing objection of showing a double image in the case of almost every transparency, due to reflection both from the front glass surface and from the rear metal coating of the mirror. The Scientific and Technical Group, which is now taking a great share in the progress of the Society, might perhaps find it possible to arrange a better system between now and the next exhibition.

The colour prints are very few in number. H. J. Campbell sends a specimen (459) of the Raydex process which by no means exhibits this method at its best, and H. S. Becke contributes a Bromoil print (460), the colours in which can scarcely be said to be produced by a process of colour photography. Four prints (455-458) by H. Ryser, showing the growth of the horse-chestnut, are presumably examples of local toning or tinting. Lastly, there are a number of exhibits illustrating a method for improving reproduction by the three-colour process devised by A. E. Bawtree. It appears to be suggested that a system of modifying the colours of an original by means of an auxiliary colour screen when making the colour-sensation negative serves for correcting the departures of the printing inks from the theoretical requirements.

THE FOX TALBOT RELICS.

The collection of apparatus and prints which has recently been acquired by the Society from the granddaughter of Fox Talbot is shown in a glass case in the museum on the second floor. It includes a number of models of early cameras employed for the Calotype process, and taking pictures ranging from 2 × 2¼ in. to 5 × 5 in. It is interesting to notice the development of Fox Talbot's methods for arranging and focussing the picture. In the early models there is a hole in the front of the camera through which the image can be viewed, and which is closed with a cork stopper before making

the exposure; in later models the picture can be arranged on a removable focussing screen. There are also shown the iron boxes, presumably to hold hot water, which Fox Talbot applied to the back of his Calotype paper during exposure in order to increase its sensitiveness. Apparatus used by Talbot for the Daguerreotype process is included in this collection, in which also are some recent photographs of Lacock Abbey by Mr. Herbert Lambert and Dr. G. H. Rodman.

TRADE EXHIBITS.

Although the Society's house does not provide accommodation for trade stands, the wall displays by leading firms draw attention to a considerable variety of photographic requisites. In the entrance hall Messrs. W. Butcher and Sons, Ltd., illustrate the employment of their "Pressman" reflex camera for telephotography. Messrs. Kodak, Ltd., show a striking collection of prints made with the "Cirkut" panoramic camera. Messrs. Amalgamated Photographic Manufacturers, Ltd., show examples of work made with the plates and papers of their constituent firms—namely, Marion and Co., the Rajar Co., and the Paget Prize Plate Co. Messrs. Thomas Illingworth and Co. devote their display exclusively to prints, by leading professional photographers on their lately introduced professional paper, "Zona." The Autotype Co. make a feature of enlargements produced in a wide range of colours by the improved Carbro process.

Messrs. John J. Griffin and Sons exhibit a large toned enlargement made on their Art-Rough A1 bromide paper, and prints on "Noctona" (gaslight) and "Goldona" (self-toning) papers. The exhibit of Messrs. Wellington and Ward consists of a striking display of prints, from negatives on Wellington plates, made on the firm's well-known grades of bromide, S.C.P., P.O.P., and self-toning papers. This exhibit is continued on the staircase communicating with the first floor. On the gallery of the latter Messrs. Kodak, Ltd., show examples of prints on the Etching-Brown Kodura paper reviewed in our columns last week. It is scarcely necessary to add that the prints are from negatives on Eastman Portrait film.

On the staircase leading from the first to the second floor Messrs. Kosmas Photographics, Ltd., have brought together quite a picture-gallery in itself of prints on their "Vitegas" paper and "Novex" gaslight paper. Mr. Foster Brigham, Mr. Herbert Lambert, and Mr. Edwin Hadley are contributors to this collection. The gaslight prints include some interesting sets illustrating the great latitude of "Novex" paper.

PIRIE MACDONALD IN LONDON.

Proceedings at a Complimentary Dinner given by the Professional Photographers' Association.

The Council of the Professional Photographers' Association took advantage of the presence of Mr. Pirie Macdonald, of New York, in London, to invite him to a complimentary dinner. This happy function took place at Gatti's Restaurant on September 14. Mr. Alfred Ellis (Past President and Chairman of Council) presided, and the following members of Council were present:—Messrs. Marcus Adams, Angus Basil, Frank Brown, Alex. Corbett, R. Haines, Herbert Lambert, R. N. Speaight, H. C. Spink, and W. H. Wedlake, and Lang Sims (secretary). Others present were Messrs. R. Child Bayley and F. J. Mortimer (respectively Editor and Art Editor of "The Amateur Photographer and Photography"), G. E. Brown (Editor, "British Journal of Photography"), T. Bell (Editor, "The Professional Photographer"), C. P. Crowther, and Bertram Park.

Cordial messages were read from the following members of Council, who, to their great regret, were unable to be present:—Messrs. Chaplin, Chapman, Gordon Chase, Chidley, Dickinson, Gray, Illingworth, Read, Turner, Wakefield, and Wheeler. The President of the Association (Mr. Swan Watson, of Edinburgh) sent a telegraphic message to the gathering, conveying to Mr. Macdonald a Scottish greeting, which was excellently intoned by Mr. Lang Sims, though he confessed that, not being a Scotsman, he did not know what it meant!

The Chairman, in proposing Mr. Macdonald's health, said that their New York colleague did not come to them as a stranger. Some of them had met him twelve years ago when he came to London, but all of them were acquainted with him through his writings, his messages, and his photographic work. His fame as a photographer of men was world-wide—(hear, hear)—but it was not so much on that account that they welcomed him, as for the fact that they knew him for the whole-hearted, right-minded, sound man that he was. (Applause.) He was one who had always cheerfully helped and advised any photographer with whom he had come in contact, and had done his level best to keep up the status and the dignity of the profession. He (Mr. Macdonald) had always believed in the giving forth of such information as he had himself acquired from others or by his own experiment; he did not keep it in a hole-and-corner fashion as some might do. It was because he had thus endeared himself to them that they were only too pleased and too anxious to gather round him and give him the heartiest possible welcome that Englishmen could give. One of his principal reasons for coming over, the speaker believed, was to try and bring about a better understanding between English and American photographers. Something of this kind was suggested at the last Congress, when a member said that he hoped to see at future Congresses not only photographers from various parts of this country, but also representatives from other countries. The time was felt to be ripe for the experiment of extending the Congresses, and giving them a wider character, and he thought he could assure Mr. Macdonald that such an idea would find an excellent backing from the Council and members of the Association. He regretted, for his own part, that he could not aspire to Mr. Macdonald's eloquence, and, indeed, he had often wished for an Englishman who could talk to English photographers as Mr. Macdonald talked to American. But his own halting speech must not be taken as a measure of the warmth with which he submitted the toast of the health, happiness and long life of Pirie Macdonald. (Loud applause.)

The toast was drunk with enthusiasm, and was given musical honours, and there was also a special cheer for Mrs. Macdonald.

Mr. Pirie Macdonald said: Twelve years or so ago, through the kind offices of Snowden Ward, I had the pleasure of meeting some of the gentlemen who are here to-night, and the only regret I have is that some two or three of the others have "passed on." It is a queer thing that as we get older the people we would like most to have enjoy what has come to our part seem to have gone on ahead of us. But that is, as my friend, the Chairman and I discussed to-night, the inevitable.

Snowden Ward was a friend of mine for a great many years, and he took it on himself to introduce me to the British

photographer. I felt at that time as though I was being received, not for any merit of my own, but simply as a friend of Snowden Ward. I felt that the respect and kindness which I received were not elicited by me, because I was a stranger, but were due to the affection which so many of you accorded our dear, old Snowden Ward. To-night I feel much the same thing. Even with the kind and generous words of your Chairman fresh in my ears, I feel again to-night as though I were being accepted, not for myself, but that much of this goodness that you are giving is being extended to me more or less vicariously, because for the moment I am the medium, the person who stands between, the link that connects you with the American end of our fraternity.

In the name of the American photographer I accept, friends, all that you have said and done. I am glad that it is so. I am infinitely more pleased to stand here as the representative of American photography than as one whom you were personally honouring. I feel this especially because now is the time—it is more to the point now than it has ever been before—that the American photographer and the British photographer—yes, and the American man and the British man—should come into touch and understand one another. (Applause.)

You have your time-honoured institutions; we are a new country. We are composed of a heterogeneous set of peoples; we have not a common sentiment as you have. We have not been a nation as long as you have, and therefore your institutions have a certain quality which ours lack. Take, for example your "Royal"—the like of that we have not in America; we have not lived long enough. We have no means of instituting such a brotherhood as the Fellowship of the "Royal." You are fortunate here in having an institution which represents, as it does, achievement, and all that goes with time. We, in America, feel that we are represented, as it were, by wooden buildings, and you by stone. We feel as though you had your feet rooted in the ground, while we are merely striving to find a place where we may stay for a while until we, too, may become homogeneous and stable. But, friends, we are much of the same type. (Applause.)

We, in America, have felt for a number of years that you have something that we should *join* with. And it has been the regret of a number of my friends—a number, if I may say it, of the more distinguished members of the craft in America—that your Congress is held at a time of the year when, owing to our commerce and our customs, it is almost impossible for them to attend. We find, in the course of our commerce, that the months of July and August, thanks to the particular variety of climate that we have, are almost impossible for the prosecution of a successful business, and the result is that—in some degree, I am afraid, the habit may be attributed to me, because I started it—you find many men who close their shops during the month of July, and others during the month of August, and some during both those months.

Let me tell you how it began. You will bear in mind that, while my name is that of a Scot, I had an English mother who was tinctured with Irish blood, and I find, curiously enough that, whether you like it or not, or whether I like it or not, there is something about me that is cantankerously Irish. (Laughter.) When I was about forty I woke up to the fact that I had been working for many years at an average of fifteen, sixteen, or eighteen hours a day, and I got a bit shaky, and things did not look right, and I thought I would "cut it out" for a little while. I telephoned up to the wife and said, "Bring me down two weeks' clothes in a bag." "Why," she laughed, "you haven't got such a thing as a bag. You've never been away except for an odd night. Of course, there's the daughter's suit case, and I have got a bag—we can *loan* you one for a week." I had bought a ticket to London—to Tilbury—and when I said, "I am going over to London for a week," the wife, being the kind of woman one can live with for thirty-two years and still like her, made no demur, but packed up the stuff, met me at a quarter before twelve, took the money that would last her through the summer, and a kiss, went away with a smile, And I came to London.

I was away a month, and when I came back I saw things differently. I had, of course, the backing of the experience of former years, but what I had seen in your country had opened my eyes. Bear in mind, of course, that we have a hundred millions of people in America, and a good deal of talent and "go" amongst them. In the State of Ohio, for instance, we have a set of photographers that, for the same area, cannot be beaten anywhere in the world. Moreover, we have a climate that makes you work. Nevertheless, on my return, I had a something in me that I had never had before, and I realised that what I had gotten from your hands was a settling-down quality—something which came from the men themselves whom I had met here. Let a man make a million pounds, if he likes, and be bereft of his friends, and the money is worthless. Let a man go to the top of Mount Everest, and put up a castle there, and have it steam heated, and put in a wine cellar, and do all the absurd things he likes that can be done with money, but prevent him looking into the eyes of a human, and it is all worth nothing.

As a result of my visit I got something of the British character back again. I got it through coming over here and shaking hands with you. And at the end of the fiscal year I found that we had even done a bit more business in eleven months than ever we had done in twelve. So thereafter I took a month off a year, and when I got to forty-five I went further and took off two months a year, and when I got to fifty I went further still and took off three months a year. Next January I am going to be fifty-five, and after that I shall take off four months a year, and when I get to sixty I shall take off still another month, and when I am sixty-five I shall work only half the year. But I am going to keep on working (because I just jolly well can't help it).

A man must not let his business absorb him to the extent of crushing out his feeling for his fellows. I am an enthusiast. I believe what I believe, because I believe so essentially in Man. I believe in man—in mankind. I believe that men are essentially square. I believe that in the main they are decent and pure and right. Now and again a man takes a match between his fingers and sets light to something in the madness of youth, and now and again a man is diseased, but those cases are rare. Men as a whole are right.

I have talked "the British man" to our American photographers for a long time. Ten years ago it was debated as to our sending a representative to Great Britain to your Congress, and if it had not been for the unfortunate season of the year in which you hold your congresses you would have been seeing many of us by this time

A very fortunate circumstance occurred this year. An Englishman suddenly made up his mind to visit the United States. He had the call to go, and most happily he carried with him the approval of British photographers. He went as their representative, and in Buffalo we were able to welcome Mr. Reginald Haines. (Applause.) We were glad to welcome Mr. Haines, entirely apart from himself, because as a sporting proposition we admire an outfit which can get one in ahead of us. We welcomed him also because he brought to us and left in our keeping the most sacred thing you have. He gave to us, in token of friendship and trust, an emblem that you all take to your hearts, and that we have accepted with the implied promise that we hold it as sacred as you hold it. He brought a Union Jack and gave it to us. (Applause.) That Union Jack is going to do a lot of good. It was a token from you. You gave us the best thing that you had, and we feel very deeply the trust that you put upon us that we may keep it clean and undefiled and wrapped round with friendship. (Applause.)

We want to know you better. We are going to know you better. You must arrange your affairs so that it is possible that our better people can come to you. It is true that if an American photographer were to leave in April or May when you have your Congress he would very likely lose the better part of a thousand "quid" by coming over, and our photo-

graphers cannot afford that. It is beyond nature to ask a man to cut into the middle of his year's business. But the time is going to come! You are going to want us enough, just as we want you, and you will arrange the date so that we can come over. Nothing will give me more pleasure than to come to you in one of your Congresses and give you the best that I have. (Applause.) And I promise that if the way is open to us I will send you ten men, better than I am, one after the other, year after year, and by the time we have used up the first ten we will have bred another ten to take their place. You need us, just exactly as we need you. The time is come when we who use the English tongue must remember that we stand alone before the world—we, of the English tongue—and that means that we of the English tongue must be knitted together, indissolubly, and this can only come about through genuineness and truth, and honesty and honour and friendship.

I do not know where Augustine Birrell got the story, but it runs to this effect. Madame de Staël was sitting beside Sir John Mackintosh on one occasion, when the subject of conversation was Napoleon, and the lady said, in her grandiloquent way, "Sir John, you know, Napoleon—Napoleon was not a man, Napoleon was a system." And Sir John said, "Magnificent, madam; magnificent." But it was only a moment later when he turned to his neighbour on the other side, and said, "But what did she mean?" Now, in this matter of friendship, what do I mean? I mean this. The most difficult thing in the world is for a man to hate another man that he has known—truly known. He can dislike him, in parts, but to hate a man whom you really know is difficult. If you have never met a man you can loathe him, but if you have met him face to face, and have seen deep into his eyes, that which might have been hatred between strangers becomes something that does have a human element in it. It may be a bitter sweet, but, after all, it does have a sweetness. And the way to arrange this matter of knitting together friends is to see the other man straight in the eyes and know him.

Years ago I was like most young men. I was not abnormal in anything—I was young. But I found that nobody absolutely agreed with me, and that I disagreed with everybody. My work was not good, and I knew it, but they told me so! (Laughter.) I found that I was becoming very disagreeable, not only to other people (which was bad enough) but to myself, which was much worse. I realised that something must be done, and here is where the Scot came in. One afternoon I "chucked the job" and went out into the country. I had an Irish terrier—and a good one, too—and he went with me. I sat down on a fence corner, lighted my pipe and had the dog at my feet, and I stayed there till after dark. But I beat the thing out, and I came to this conclusion, the basis of the entire philosophy of my life—and if it is no good I am an unutterable failure—that as long as I live I am going to find in man—in every man and woman and child I meet—a something that I can like, and I will take that to my heart and cherish it and I will never mind about the things I don't like. Now, time and again I run across a man whom I find to have views diametrically opposed to mine, and I cannot abide him easily, and, because I am not going to have him upset my humour for the next fifteen friends I meet, I simply side-step him and leave him alone: I let him "gang his gait" and leave him alone. But put your arms around the man you can like! I believe that if there is anything in those photographs of mine that is of any value, it is that the men look out of them as though they like the person that looked at the photograph. The only possible value there can be in a photograph that is made for a woman is to have the man look out of the photograph as though he loved her. You can make things as craftily as you choose, and as beautiful as you like; you can have them pass ten thousand juries, but if the photograph you made was intended for the man's mother, and it does not make the man's mother want to take the thing to her heart, it is not of any value. That photograph must have in it the appealing power of love. And we must bear in mind that that which we utter is returned to us in kind. If you are a grouch, everybody grouches with you; if you are a miser, everbody—well, everybody is most careful. If you really like a man, he is a hard one that don't come across and like you *some*. If there is anything in my photographs it lies in the fact that I like the man I am portraying. (Applause.)

About three years ago a man came into see me who had made his money in a sweat shop. He was fat under the chin through eating goose-liver patties and that sort of thing. He had been driving a bunch of girls, sweating them down, getting the last farthing out of them. He sat down in the chair I indicated and I asked him to move this way or that. "Just as I am," he said. "Yes," I said, "just as you are, but——" "But nothing," he said, "I want it made as I am." "Well," I said, "you can have it made in exactly the damn way you like, and right down at the end of the hall, to the left, is the door, and up and down the street there you can find a bunch of people who will make you the way you wish to be made, and I will wish you a very good morning." (Laughter.) I wasn't going to break up my temper for the whole day on his account, nor spoil the seven or eight sittings I had to follow in order that I might get money out of that beast. He could jolly well keep it if he wanted. (Laughter.) That is the way I treat the problem, but I assure you that it happens very rarely, for, as a rule, people do respond.

There are some of you, beyond doubt, who have not met a sufficient number of Americans, and you are probably possessed of an idea that Americans, as a whole, are difficult. From some point of view they may be, but you are going to find them just the same kind of men as you are if you will take the trouble to go after them and meet them; and, remember, for every step you take towards them they will take two towards you. It is the climate we live in. We have got the adventurousness of Great Britain over there. That spirit of adventure, combined with the climate, does bring with it certain rawnesses; but we have got it, and it is this fact which makes Americans take the two steps towards you. Every now and again you are going to find an American "blighter"—a bad one. When you have met him, and he annoys you sufficiently that you are uncomfortable, don't say, "He is an American"—don't say that. The thing to do is this: don't say anything, close your eyes and think of a British "blighter" that you know who is just as bad as he is, *pair them off*, and then forget about them. (Laughter and applause.)

Great Britain has always been the clearing-house for adventure and ideas. For centuries she has been a clearing-house. Here is the logical centre—right here! Not Milwaukee, St. Louis, Kansas City—*here* is the place where you should have the talent of the world come. If you want us we Americans will do our share; you make things so that we can come and we will come. (Applause.) I have come here, not only to talk to you, but to talk to the Rotary Clubs as well. I have been trying to get Englishmen, who have lived on a little island, to realise the people who have lived on a great range of country—people with rather different dispositions, due to environment. I have come here to try to get them to reconcile themselves to one another, bearing in mind that we have got one great thing under us all—we speak the English tongue.

I do not want to go away without stimulating in one or more of you the idea that you must come over and see us—that you ought to come over and be a part of us, as we are a part of you. I have not any better sentiment than that.

I have not anything more to say except that, coming here as representative of the American photographer, it has given me infinite pleasure to be with you. I am able to speak for as sporting a set of men as there is in the world, and in their name I try to tell of the pleasure it gives me to speak to these—(with the exception of the fact that I happen to

be a naturalised American)—to these, my fellow countrymen. (Loud applause, after which Mr. Macdonald's health was again drunk with enthusiasm.)

The Chairman then presented to Mr. Macdonald a souvenir of the occasion to convey to Mrs. Macdonald, and also a small British and a small American flag. Mr. Macdonald made a happy acknowledgment of the gifts, and said that, coming from friends of his, he knew exactly what "the little woman now waiting in the hotel" would say when he handed the souvenir to her.

THE LONDON SALON OF PHOTOGRAPHY.

(*Concluded from page* 549.)

The Child Portrait.

Without any disparagement of the freedom and accidental character of the photographic, as against the traditional portrait, it must be admitted that in capable hands the latter secures something in the way of rightness and charm which the former is apt to miss. One sees this in the traditional method of the mezzotint portrait which Mr. Marcus Adams adopts with a very unerring sense of style in "Bubbles' Sister" (80), "Rosemary, Daughter of Lady Lucas Tooth" (33) and (92), and other examples. Sometimes the oval border is adopted, which, together with the peculiar softness of texture and equableness of dark passages, reproduces the character of the mezzotint engraving very successfully.

The reverse of these traditional conditions is seen in the extremely interesting child portrait which L. Fleckenstein calls "His First Overcoat" (210), thus giving it claims to *genre* work as well as portraiture. The little fellow stands just within a sunbeam which falls upon the wall and floor, and the effect of this sunshine is surprisingly convincing; in fact, sunshine is not better rendered in any figure subject in the gallery, though J. A. Lomax runs it close in "Sun Jazz" (27), where the motive seems to be more the shadows of a pergola or railing structure cast upon a sloping wall than the presentment of the child, who catches some of the effect. Herbert Lambert's "Denis" (19) comes half-way between old traditions and new methods with a print in a high key of a captivating little boy, at half figure nude and with rather "beady" eyes. Even better is his "Ruth" (116), whose hair *à la* Golliwog and taking smile of controlled self-consciousness is quite irresistible. Angus Basil's "Child" (44) shows skilful lighting and well-caught expression. The light scheme adopted by W. Harold House in "Boy and Shadow" (59) belongs to the photographic era, although its originator, Mr. Wm. Cadby, might have been inspired by pencil or silver-point drawings. But though a later resource in camera work, it looks a little old-fashioned to-day, when the tendency is to produce rich and strong work. J. Beardsworth sends "A Dirty Little Rogue" (82) in a vignetted setting, which is puzzling at first sight until one has discovered that the baby is not in foamy water just below the edge of a quay, but peacefully reclining on some texturous material beneath the apron of a "pram." A Longman's meditative baby is very humorous. Its name is "Eunice" (288), and its pose is unique. Amongst Mr. Marcus Adams's collection of children one of the most striking is "Dorothy and June, Daughters of Mrs. Clifford Grey" (131). The younger seems more like a baby boy than a daughter. This little composition is extremely successful, and the nude flesh of the little ones is given with much plastic realism. Another group in a different manner is "Meddlesome Matties" (110), by Janet Allen. It shows three little girls busy at some mischief.

Whilst speaking of groups, I must distinguish Dora Head's charmingly animated girls of different ages in "Stories" (241), of which the arrangement is both ingenious and delightful. An out-of-door group of much skill likewise, and comprising a quantity of figures, is "The Quarrel" (327), in which Walter Lee has quite succeeded in making a lot of schoolboys act with commendable effect and lack of self-consciousness. "The Good Story-teller" (257) is another clever piece of grouping—a bevy of lively girls hero-worshipping a young man.

Nudes.

As usual, Bertam Park excels in the nudes. He has the right sense. He knows why the figure is good pictorially, and he never makes a mistake. All his examples have beautiful lines and exquisite modelling. As a rule, he has adopted this year a delicate scheme of rather flat lighting, which gives his gleaming bodies an alabaster quality rather new to camera work. But in "Nude" (17), a highly modelled girl sitting on a table, he supplies a forcible contrast to this general rule. In No. 72 he adopts a low tone. The upright standing (98) is evidence of Mr. Park's good fortune in models. There is in this example a rare physiological condition, tight and well-braced skin and integuments which make relaxed and pendulous flesh impossible, and so the figure escapes associations of realistic undressedness and secures a classic ideality. The squatting and weeping "Figure Study" (85), by H. A. Neumann, has also a touch of this classic grace and sculpturesqueness. It should be stated, however, that Angus Basil's "Nude" (161) is in a style of modelled flatness similar to the best of Mr. Park's, and is very prettily posed. Other figure studies are smaller, and used very effectively sometimes as accessories to landscape ideas, whilst what remain are in the category of dancers and gymnasts. One or two figures half clothed are skilful examples of pictorial work in this class, noticeably Dr. H. B. Goodwin's "Figure Study" (185), and W. Eide's "Illustration for a Fairy" (129), whilst Francis Jay's "En Plein Air" (168) is a remarkably clever combination of nude damsels and a sea shore, and eminently pictorial and bright.

Landscapes.

It cannot be said that landscape is a strong section of the show, because the proclivities of the selecting committee were evidently towards figure work; but what there is of landscape includes some first-rate work. Perhaps the things that stand out are Charles Job's bright and rich "On the South Downs" (163), its great merit being superb sky-luminosity; G. F. Prior's well-composed "As the Evening Shadows Lengthen" (251), a river-side street, having much quality and truth and a fine sky; and S. Brigden's "England" (304), a noble composition of a sunny lane crossed by shadows. F. O. Libby's landscapes are finely conceived, but he often gets off the mark with his suns and moons, and he persists in using an unpleasant blue tint for his prints. "The Lake Below the Hills" (203) is perhaps his best work from the point of view of tone values and recession of planes, because the subject lends itself to force in these directions, but "The Slow Moon Climbs" (108) has fine gradation, though the moon itself is unconvincing.

J. H. Anderson's "Windmill" (22) is an excellent composition, but its tone-values are not easily explicable. A bald and flat effect and a poor composition cannot rob the interest from "The Moon of the Red Gods" (31), in which Laura Gilpin has bravely carried through a new idea in making luminosity an all-sufficient subject in itself. A. G. Buckham makes a highly effective landscape out of great cumulus clouds (43), very dramatic in their force, a peep of fields far away down and an

aeroplane. Lionel Wood gets interest into his rather empty "Edge of the Beyond" (77) by the introduction of a little nude figure. These edges of foreground hills with no beyonds to speak of have been often tried, but no landscape is really pleasing without middle and distant vertical planes. Dr. R. S. Lovejoy also uses a figure—a clothed climber—to give force to the awful feeling of the vastness of his beyond in "The Abyss" (78). The finest of Alex. Keighley's several landscapes is "An Old Château" (87), because in that he preserves the true effect of sun and shadow on the building; in "The Monastery" (81) he puts his highest light, and it is very high, upon the roadway, though the sky is dark comparatively. His new departure in subject matter, "A Swirl of Waters" (90), is a very fine thing. Mr. Keighley's other subjects are good compositions with the life and interest knocked out of them by a treatment of monotony and departure from natural justness of values. "White Birches" (101) is a good subject by N. P. Moerdyke in the ugly blue tint beloved of American workers. The lines of H. N. van Wadenoyen's "Cliffs at Aberdaron" (118) are splendid and its sky and general tones are fine. Another striking work is "The Cloud Majestic" (122) chiefly because of its effective low horizon. "Evening Quiet" (130), by W. B. Bradford, is true and has an intense mood. Some real pictures of sunlight are noteworthy, particularly T. O. Sheckell's gateway into which two little people are entering whom he calls "The Adventurers" (136); and likewise his lovely "Paths of Youth" (262) with its two children. L. Misonne sends a nice collection of his very individual work, of which I prefer "Dans la Lumière" (209), because it is so satisfactorily centralised; but "Promenade Matinale" (208) is nice and sunny. Sunny also is "An Outback Australian Home" (223), which would be better if there were "a way out" at the back. Hugo van Wadenoyen, jun., has triumphed with the broad masses of light and shade in his "Houses at Cowbridge" (234). Indeed, houses and street scenes are very amenable to sun effects by photography. J. A. Lomax profits by this fact in his excellent "Shadow of a Chimney" (252) on the side of a white building. "The Shadow" (282) is another example, by T. J. Lewis, of the pictorial possibilities of a wall or two in the matter of light and texture. In "Terror" (302) we have not only splendid light but a dramatic composition of figures and rocks by H. A. Avery. "The Staithe, Whitby" (409), is a print of fine quality wherein H. Bairstow has dealt with light in the distance seen through the dark beams of the wooden erection in the foreground. In a quieter mood is his "Lonely Calvary" (435), an impressive mountain scene.

Quiet also, and dignified compositions, are two works by J. M. Whitehead, "A Dream of Raploch" (371) and "Craig Millar" (368), which has a fine sky. Were there more light in the sky of S. W. Shore's "Summer Evening by the River" (383) it would be a most successful landscape—a new departure for this well-known portraitist. E. M. Pratt's "Canyon of the Metropolis" (331) is noble and romantic, and so is Bertram Cox's splendid view of the Admiralty Arch called "A City Portal" (256). He has never surpassed this bright and busy vista, showing superbly through the architectural grandeur of the arch. A similar classic breadth and magnificence is in A. H. Blake's "Liverpool" views (47 and 171). A. C. Banfield's "Piccadilly" (152) seen from a reasonable distance is a capital London impression of a bright yet misty day. Another splendid London scene is "By St. Paul's, Covent Garden" (9), by G. F. Prior, proving in a remarkable way how a keen observation guided by a beauty sense can find glorious pictures in the most unthought of places.

To turn to moonlight we have "The Quiet Traffic Hour" (20), E. M. Pratt, a street empty but for cabs seen from a high standpoint; "Nocturne" (66), by Karl Struss, a wonderfully true effect also, with its gleaming lamps, and very decorative except for the aggressive line of the great bridge. Hector Murchison in "The Pit" (244) and "Tubs" (157) gets the fascination that lurks in great industrial works. H. C. Torrance does the same in his wilderness of trucks in "Pittsburg Steel Works" (365). It was to be expected that somebody would photograph the tower of St. Magnus as revealed by the demolition of the Pearl Society Building at London Bridge, and M. E. Selby has done it splendidly in "The Old Order Changeth" (291). One or two exceptionally good skies remain to be noted; "The Foot of the Downs" (299), by Bertram Cox—a fine subject; T. O. Shekell's "Banks of Drifted Snow" (261); "Winter Landscape" (253), by L. A. Olsen; and "Pepper Tree" (276), by J. P. Edwards.

Amongst marine subjects there is also a notable sky in "Surf Canoeing" (37), a beautifully choice print by Arthur Ford. It is very lively, as is F. J. Mortimer's vivid yachting piece called "Life" (42). "The Sea Road" (89) is another good thing, the best perhaps of F. O. Libby's works. There is also life and sparkle in Rev. J. V. Haswell's "Rings" (141)—a surf scene, the rings being made by four girls in the water and the foamy waves around them. John H. Anderson gets sparkle on the water beneath the dark sails in his "Luggers" (153); but his finest picture is the beautifully tender "Close of Day" (149), with its calm mists and colourful sky. Perhaps the strength of F. J. Mortimer's sky detracts a little from the interest of his battleship in "Scrapped" (162). His "August" (170) is the limit of liveliness—a bird's-eye view of the sands at Ramsgate or Blackpool or some equally reposeful spot. L. J. Steele's Venetian views (56 and 179) are a contrast to this in their quiet peace, but they are sparkling and rich nevertheless. The "Sand Dunes" (220) of J. A. Lomax are soft and sweet with one sharp accent of some thistle-like growth in the foreground.

More than one exhibitor has succumbed to the romantic eeriness of dark woods and gaunt dead trees. These pictures are all good in idea and treatment. "The Enchanted Wood" (230), J. E. Paton, relies on a forceful light and shade. "Skeleton of the Forest" (236), E. M. Pratt, is a gruesome stump, and another is "Sentinel of the Night" (281), by Ernest Williams.

I have not yet spoken of a fine landscape design by N. P. Moerdyke called "Eucalypts" (143), in the blue tint unfortunately; nor have I mentioned a first rate architectural subject by M. N. Bremon, "The Portico" (154), which has all the style and grandeur of a Piranesi design. The exquisite quality of L. J. Smith's back-yard scene, "The Water Butt" (259), certainly deserves mention, and it would be a shame to conclude a notice of the Salon without reference to the works by R. Polak, which whilst no longer new, are as good as ever. Some I know to have been done years ago though shewn for the first time here. "The Message" (189) is perhaps the best. In "Back from Market" (188) I think the pail the maid is holding smacks of an anachronism—a rare thing indeed in M. Polak's studied reconstructions.

F. C. Tilney.

Radiographs at the R.P.S.—Mr. N. E. Luboshey asks us to say a few words of explanation in regard to the many examples of X-ray photography which appear under his name in the R.P.S. Exhibition. Although the exhibits have been brought together by him, most of them represent the work of hospitals, in particular King's College Hospital, and he is obtaining permission to identify the exhibits (by inscriptions thereon) with the individual authors more closely than is done in the catalogue.

An M.P.'s Cameras.—Sir Richard Cooper, the Member for Walsall, has looked forward to the Parliamentary holiday because it gives him leisure to devote himself to photography. He has, the "Evening News" tells us, a fine collection of cameras, and always when he takes a holiday you will find two or three of them among his luggage. He is not content merely with taking pictures. He likes to develop them himself. Recently he has launched into cinematography.

Houghton's Bulletin for September contains particulars of new styles in mounts and mounting materials, and an announcement of a reduction in the price of a series of sketch boards. Any portrait photographer whose name is not on Messrs. Houghton's books for the receipt of the Bulletin may obtain it by sending a postcard to 88-89, High Holborn, London, W.C.1.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

SUNDAY, SEPTEMBER 25.

Hammersmith (Hampshire House) P.S. Outing to Chertsey.

MONDAY, SEPTEMBER 26.

Bowes Park and Dist. P.S. "Transferotype." J. Brown.
Society of Photographic Writers, Liverpool.
South London P.S. "Birds and their Nests." F. P. Bayne.

TUESDAY, SEPTEMBER 27.

Hackney P.S. "Easter Holiday at Harlow." A. J. Linford.
Manchester Amateur P.S. "Un Impressione Italiano." H. E. Johnson.
Morley Photographic Society. "Enlarging." H. Grainger.
Scottish C.W.S.C.C. (Glasgow). "Trimming and Mounting."

THURSDAY, SEPTEMBER 29.

Hammersmith (Hampshire House) P.S. "An Ancient Order of Chivalry." H. W. Fincham, F.S.A.
Kiuning Park Co-op. Soc. Open Night.
North Middlesex P.S. "Epping Forest and Neighbourhood." F. G. Emler.

SATURDAY, OCTOBER 1.

Glasgow and W. of Scot. Amateur P.A. Excursion to Inverkip.
Hammersmith (Hampshire House) P.S. Outing to Oxhey Woods.
Scottish C.W.S.C.C. (Glasgow). Outing to Glasgow Harbour.

CROYDON CAMERA CLUB.

Mr. F. C. Reynolds gave a highly interesting chat on "Nickel Coinage," contrasting it favourably with the weighty copper of this country. Apart from nickel coins being liable to be mistaken for silver by the product of modern methods of education, there is a lot to be said in their favour. A central hole, adopted in some countries, ensures their not being confused with silver.

Many nickel coins of all countries were passed round, and, owing to the nature of the metal returned in safety. Speaking generally, they would meet with approval with any cult of the ugly. In the discussion, Mr. Harpur said he invariably carried in his pockets sundry copper coins which were a safeguard against rheumatism, and he doubted whether nickel would be so effective. Others thought this metal would be equally potent.

Commercial & Legal Intelligence.

CANVASSING FRAUDS.—At the Essex Quarter Sessions last week, Sidney Meider, 36, described as an artist, of Morris Road, Leytonstone, was indicted on four counts for obtaining money by false pretences from persons living at Woodford, Balham, and Walthamstow. Mr. C. E. Jones said prisoner's method appeared to be to call on various people in the district representing that he was a discharged soldier trying to earn an honest living, and promising to enlarge photographs, free of charge, on condition the customers purchased frames for the enlargements. In the four cases in question money was paid for the frames, but none were received, and it was alleged that the prisoner had no means of making the frames. When arrested by Detective Sergt. Hider prisoner said: "I am done. That is the worst of having a big family. They take all the money." Prisoner, on oath, said the frames were not delivered in consequence of his orders being cancelled on account of the coal strike. He told his customers he was a discharged soldier, but he had never worn a silver badge. He had seven children. He had every intention of carrying out his bargain. Prisoner was found guilty, and it was stated that he was a deserter from the Army. There was a conviction for a similar offence, prisoner calling upon people shortly after the Silvertown explosion and asking to execute enlargements of photographs of people killed. The Chairman said the prisoner had been convicted of a series of contemptible frauds. He would be sentenced to two years' imprisonment.

NEW COMPANIES.

CINEMA ART, LTD.—This private company was registered on September 12 with a capital of £750 in £1 shares. Objects: To carry on the business of makers of and dealers in artistic photographs for the use of or re-sale by printers, publishers, stationers, booksellers, lithographers, stereotypers, photographers, engravers, die-sinkers, etc., and to adopt an agreement with Ralph Aaron Solomon. The subscribers (each with one ordinary share) are: Ralph Aaron Solomon, Ranfurly, 136, Walm Lane, Cricklewood, N.W.2; Stanley A. Jarrett, 21, Macfarlane Rd., Shepherds Bush, W. 12, solicitor's clerk. The first directors are: Ralph Aaron Solomon (permanent managing director), David Albert Abrahams and Alfred Edward Boudy. Registered office: 25, Shaftesbury Avenue, W.1.

W. DALBY, LTD.—This private company was registered on September 10, with a capital of £1,000 in £1 shares. Objects: To carry on the business of opticians, photographic supplies dealers, etc. The first directors are:—W. Dalby, 167, Charnwood Street, Leicester; K. C. Biggs, 51, Highfield Street, Leicester. Qualification: 1 share. Registered office: 167, Charnwood Street, Leicester.

C. WINSTON AND CO., LTD.—This private company was registered on September 7 with a capital of £500 in £1 shares. Objects: To carry on the business of opticians, sight testers, lens makers, manufacturers, importers and exporters of and dealers in optical instruments, photographic apparatus. The first directors are: Herman Cahal, 53, Herbert Street, Cheetham, Manchester; Mrs. Mary Winston, 367, Bury New Road, Manchester. Qualification: £150. Secretary: C. Winston. Registered office: 367, Bury New Road, Higher Broughton, Salford.

News and Notes.

DEATH OF MR. THOMAS WHITE.—We regret to record the death of Mr. Thomas White, of Biggin Hill, Kent, a former Mayor of Lewisham, which occurred at the age of 68. Locally he was widely known as Liberal Registration agent, as a Borough Councillor and in many other capacities. Born in Southampton, Mr. White came to London in 1869. After establishing a business as a photographer in Southwark, he went to live in Lewisham in 1882, and with a studio in the High Street continued his photographic work for many years.

CAMERAS ON THE "QUEST."—On Saturday last the "Quest," under the command of Sir Ernest Shackleton, sailed from the Thames on her 30,000 miles voyage to the Antarctic, and the little-known islands of the Pacific. We are told that the number of cameras produced at the last moment was, considering the dock regulations, prodigious. Hundreds of cameras clicked on land, while on board the official photographer, Mr. J. C. Bee Mason, was turning the handle of his cinematograph, and Mr. Rowett and half-a-dozen others were snapping the scenes from the bridge.

THE POLYTECHNIC SCHOOL OF PHOTOGRAPHY.—The session of the classes at the School of Photography, Regent Street Polytechnic, begins on Monday, September 26 next. The evening classes include a series of lectures on the optical and chemical principles of photography by Mr. L. J. Hibbert, each lecture being followed by a class in which students will carry out practical experiments bearing on the subjects of the lectures. Courses of practical instruction in studio portraiture by daylight and by artificial light are given by Messrs. Edgar Clifton, H. C. Standish, and Robert Johnson, whilst the technique of negative making and printing is the subject of a practical course by Mr. H. G. Harrison. Enlarging in bromide, platinum, and carbon is the subject of a special course by Mr. Clifton, and training for the photographic retoucher and colourist is provided by classes under the direction of Mr. A. J. Lyddon, Mr. R. W. Wicks, Mr. F. W. Harrison, and Mr. Johnson. A course of training in the methods of commercial photography is provided by the classes under the case of Mr. W. A. Sivyer, and Mr. Johnson instructs in the making of life-model studies for advertisement purposes. When it is added that the school also offers a course of instruction in photo-engraving and three-colour block making taught by Mr. G. C. Laws, it will be seen that the whole field of professional and technical photography is included

within the curriculum. Individual students may obtain lessons privately in any special subject during the daytime. The prospectus of the evening classes is now published, and may be obtained on application to the Polytechnic, 307, Regent Street, London, W.1.

CLASSES IN PHOTOGRAPHY.—A course of instruction in photography, consisting of twenty-four lectures and demonstrations, begins at the Borough Polytechnic Institute, Borough Road, London, S.E.1, on Monday next, September 26. The class, which is under the charge of Mr. Robert Coombs, is held from 7.30 to 9.30, and the course provides instruction in all the ordinary processes of negative making and printing. For students under the age of 18 the fee is 10s.; 20s. for those above that age.

At the Battersea Polytechnic, Battersea Park Road, London, S.W.11, Mr. E. Senior again superintends the courses of elementary and advanced instruction in photography. The former is held on Tuesday evenings, beginning September 27; the latter on Thursday evenings, in each case from 7.30 to 10 o'clock. The first hour is devoted to a lecture, and the remaining hour and a half to practical training. The fee for each class is £1. Mr. Senior also conducts a special course on Tuesday evenings, from 7.30 to 9.30, in enlarging. The fee for twelve lessons is 10s.

At the South-Western Polytechnic Institute, Manresa Road, Chelsea, London, S.W.3, Mr. Senior is also the lecturer on photography and superintendent of a practical class which is held on Monday evenings, beginning September 26, from 7.30 to 10 o'clock. As at Battersea, each evening is occupied by an hour's lecture and subsequent practical class instruction. The fee for the course is £1. Those interested in photo-micrography should note that a course of eight practical demonstrations in this branch of work, including the photographing of etched surfaces of metals and alloys, will be given by Mr. Senior at the South-Western Polytechnic, beginning Monday, May 1, 1922. The fee for the course is 5s.

IDEAL HOMES EXHIBITION.—The awards in the photographic competition organised in connection with the Ideal Homes Exhibition, at Glasgow, have been made, the judges expressing the opinion that the standard in classes I, 2, and 3 was very high. They were, however, disappointed with the entries of contact prints, particularly in class 5. Altogether over 3,000 prints were submitted for adjudication. The awards were as follows:—Class 1. (Landscape and Seascape): First prize (£10 10s.), Charles A. Allan, Kilmarnock, 'The Sentinel"; second prize (£5 5s.), John G. Pratt, Greenock, "At Break of Day"; third prize (£3 3s.), J. Arthur Lomax, Cardiff, "Sunlit." The following extra awards, each of £1 1s. were made to:—H. G. Allan, Southport, "The Lye Mun Pass"; Dan Dunlop, Motherwell, "A Normandy Crucifix"; Miss Stella Malcolm, Edinburgh, "In Old Dinan"; G. F. Prior, Chingford, "April Sunshine"; Louis F. Steele, Portsmouth, "A Venetian Study"; John A. Stewart, Glasgow, "Duntreath and Dungoyne."

Class 2 (Portraiture and Figure Studies): First prize (£10 10s.), Mrs. G. A. Barton, Sutton Coldfield, "Mother and Child"; second prize (£5 5s.), J. Arthur Lomax, Cardiff, "Girl Drinking"; third prize (£3 3s.), H. Y. Summons, Virginia Water, "Ambition." The following extra awards, each of £1 1s., were made to:—Angus Basil, London, "Nude Study"; Maud Basil, London, "A. A."; Bruce Cameron, Milngavie, "The Toiler"; D. J. Donovan, Frinton-on-Sea, "Little Women"; Dan Dunlop, Motherwell, "The Smiddy."

Class 3 (Architecture): First prize (£10 10s.), H. Y. Summons, Virginia Water, "Thebes"; second prize (£5 5s.), Dan Dunlop, Motherwell, "St. Jargues"; third prize (£3 3s.), Bruce Cameron, Milngavie, "St. Pierre." The following extra awards, each of £1 1s., were made to:—H. G. Allan, Southport, "The White Tower"; W. Bailey, Leicester, "In the Tudor Period"; W. S. Crocket, Glasgow, "Mars Work, Stirling"; J. H. Leighton, Bradford, "Hurstmonceaux"; W. H. Reece, Walthamstow, "The Admiralty Arch."

Class 4. Any subject (three contact prints of quarter-plate size or under on one mount): First prize (£10 10s.), Rev. J. V. Hascold, Huddersfield; second prize (£5 5s.), H. Y. Summons, Virginia Water; third prize (£3 3s.), Mrs. G. A. Barton, Sutton Coldfield.

Class 5, for amateurs who had previously received no award. Prizes of £10 10s., £5 5s., and £3 3s. were awarded in the following sections:—A, for six pictures of a happy holiday: 1, W. M. Bishop, Motherwell; 2, J. M. Duncan, Paisley; 3, Peter F. Harper, Glasgow. B, for three prints of any subject: 1, James Miller, Paisley; 2, W. J. Clutterbuck, Norwich; 3, Arch. Weir, Glasgow. C, for three landscapes or seascape prints: 1, James Londsay, Glasgow; 2, Robert Clark, Glasgow; 3, W. C. Wood, Glasgow.

R38 DISASTER PHOTOGRAPHS.

To the Editors.

Gentlemen,—Mr. T. C. Turner's remarkable experiences, and his claim to have taken the first pictures of the R38 disaster, have created a smile among the actual Press photographers of Hull. We flatly deny that Mr. Turner was first on the scene, and we can prove this statement if necessary. It would be interesting to ascertain exactly how many pictures taken by this well-known studio photographer appeared in the Press. The undersigned include the staff photographer of the "Hull Daily Mail," a well-known professional, and the operator of a Hull Press photographic agency, who were all quite equal to the occasion. We were unquestionably the first on the scene and secured the best pictures that were obtained, both from a journalistic and technical point of view. The fact that some of us were making subsequent trips to the scene of the wreck when Mr. Turner saw us does not justify Mr. Turner's ridiculous and incorrect claim, and we strongly object to it.—With compliments, we are, yours, etc.,

G. H. HARNESS, F. OVERTON, E. W. WATSON (Watson Bros.).

To the Editors.

Gentlemen,—Professional friends have pointed out to me a somewhat remarkable article in a recent issue of your paper by Mr. T. C. Turner, photographer, of Hull. On perusing this, one finds some amazing reflections upon the Press photographers, and also the editors of the newspapers in London, together with a suggestion that Mr. Turner was the first on the scene, and so created something in the nature of a feat of which to be proud. He says the Pressmen just managed to record a picture an hour after the occurrence. This statement is not true and an unfair one. I am prepared to prove that I was there with a reflex camera no later than 15 minutes after. I was in a taxi which I directed down side streets to avoid the crowds that were rushing to the scene.

For the information of your readers, I may point out that Mr. Turner is essentially a studio worker and a portraitist. His work in this direction is greatly admired by many, including myself. Personally, I am essentially a focal-plane worker. All photographers know what a wide gulf there is between action photography and portrait work. An event like the disaster to the R38 is not a studio job. It would be interesting to know how many of Mr. Turner's wonder photographs ever saw the light of day in the Press. "The proof of the pudding is in the eating." We always welcome competition, but I am prepared to state that the pictures which were issued by my agency were vastly superior both from a journalistic and technical point of view to any of Mr. Turner's taking. They ought to have been, too, seeing that this is my line. My work is known in Fleet Street, where pictures are only selected on their merits. It is for this reason that when Mr. Turner makes the suggestion that the Press photographers were not equal to the occasion I, along with other professional colleagues, raise our hands in protest.

Let me inform Mr. Turner that it was my duty as the appointed and recognised special photographic correspondent of the principal London and provincial picture papers, dailies and periodicals, to be there first, and I was. I am sure that I have no desire to make a song about being there first. The police might

just as well write an article about the wonderful work that they did and send it up to their periodical. Mr. Turner, in raising this point, is showing very bad taste, I think. Surely those brave airmen did not meet such an awful death just to provide Mr. Turner with something to crow about. Genuine Press photographers can always be identified on these sad occasions by the quiet way, despite technical difficulties, in which they carry out their duties of recording the scene so that (in this case) the whole world may see what had happened to the world's greatest airship. I am a member of the Institute of Journalists; Mr. Turner is, of course, not. The recognised pressman has a right to be there. The studio man has not. What right had Mr. Turner to be there at all? What paper does he represent? Let Mr. Turner in future stick to his studio work and leave the Press photographers alone. The disaster was far too terrible to be the mere subject of pictures for Mr. Turner's windows with the lights burning till a late hour as an advertisement. That is the sole reason Mr. Turner went out to the wreck for, and I do not think it is very creditable. Yours, etc.,

EDWARD W. WATSON,
Proprietor of Watson Bros., Press photographers.
12, Charlotte Street, Hull.

[As these letters reached us too late for insertion in our issue of last week, we submitted proof of them to Mr. T. C. Turner, whose reply appears below. We think the absence of salvage vessels (and of men on the envelope) from Mr. Turner's photographs is sufficient evidence of their production at an earlier time than those by Mr. Overton, which are sent to us by Mr. Overton in accompaniment of the further letter which appears below. The viewpoints from which the floating wreck was photographed differ considerably, but it is possible to say with reasonable correctness that the last of Mr. Turner's photographs to be taken shows the wreck in approximately the same state as does the first of Mr. Overton's.—EDS., "B.J."]

To the Editors.

Gentlemen,—I am obliged for a copy of the letter sent to you by Mr. Overton and endorsed by two other local Press photographers, Messrs. Harness and Watson. I called upon Mr. Overton for an explanation of his letter and purchased a set of his pictures, which he assured me were his *earliest* after the disaster. You will see by these prints that his contention cannot be maintained, but as he has apologised there is an end as far as he and I are concerned.

Mr. Harness, the only one of these gentlemen I knew, is a Press photographer of repute in the district and a staff photographer of the "Hull Daily Mail." This paper published the night after the tragedy, and above my firm's name, the large broadside view "being the first photograph to be taken after the disaster."

Mr. Harness did not see the accident, but says that after receiving a telephone message he cycled to the pier, secured a rowing boat, and in it reached the scene of the wreck. "He thought it was from 2 to 2½ miles away." If this had been a correct guess it would prove a long and arduous row.

Now I had actually witnessed the accident in all its dreadful detail, knew exactly where to find the wreckage, and when, after a race to the pier, I sprang on the already moving tug, I was quite sure the advantages were all on my side. I certainly saw no trace of photographic activity in the boats near the wreck, and very great enlargement of the negatives has failed to reveal the figure either of Mr. Harness or of Mr. Watson.

The matter is scarcely of sufficient interest to intrude on your valuable space, but for Mr. Watson's greatest share in the letter, and his suggestion of antagonism between Press and studio photographers. He appears to have been the actual author. I could not at first obtain his address from the other two signatories, but after an arduous search I discovered his establishment at the top of a building in Central Hull. On a door labelled Watson Bros. was a notice "out" and a paper clock face announced "return at 12. Please put messages under door." As no member of the firm had turned up by 12.30 I had to leave my card under the door with a request for an interview at my own place.

When Mr. Watson called I asked him to substantiate his contention by producing his own pictures and by showing me his journalistic account of the catastrophe.

It seemed a simple affair; the photographs themselves would prove the position of the tide and the gradually collapsing wreckage must tell its own story. Mr. Watson refused both requests and somewhat discounted the claim to the best "from a journalistic and technical point of view" by saying he had not witnessed the accident himself. He had jumped into a taxi—a rare bit of luck to find there and then—and on reaching the pier he too had secured a rowing boat! As Mr. Watson neither apologises nor is willing to establish his case in the only possible way, I fear there is nothing more to be said. Your readers will form their own opinion on the fairness or otherwise of this attack.

I sent my account of the disaster to the "British Journal" and to my friends of the P.P.A. and the profession generally because I thought it would interest you and them, coming from a *photographer on the spot*, the very, very spot where the fatal curve was made. I entirely disclaim any intention of wounding the susceptibilities of the local Press photographers by stating I made the first exposures of the wreck from the Humber, a claim which I venture to think is still holding good.

The writer of the second letter, Mr. Edward W. Watson, of Charlotte Street, Hull, is also the author of the first signed by Messrs. Overton, Harness and Watson. When his letter is not positively childish it is rude, and evidently written to produce the impression that in giving the account of the airship disaster my motive was to attack Press photographers. Anyone of average intelligence would see that outside the simple narrative itself my comments were directed to criticising the unfairness of those newspaper editors who leave out a professional's name and address, accepting at the same time offers of service at "fees which in *many cases* are almost beneath contempt."

Who is Mr. Watson to take up this position? I resent his interference, because there is no cause for it. He asks a good many questions which I would be happy enough to answer were they of a less personal character or at all interesting to my confrères.

Quoting from his last letter, "All photographers know what a wide gulf there is between action-photography and portrait work. An event like the disaster to the R38 is not a studio job." I suppose Mr. Watson is trying to say a Press worker possesses some quality a man of the studio does not. Ridiculous! Is there any *live* man of decent education, good eyesight, and possessed of suitable apparatus, who is not a better *Press* photographer if to his knowledge of focal plane work he adds an expert's training in studio work?

The established studio worker has also other advantages. As a business man, a citizen well known in his city, probably paying heavy rates for a prominent position, enjoying the resources of a well-appointed centre—artificial light apparatus of every kind, enlarging rooms, artists and staff of assistants—he must be in a better position than the average Pressman, often of limited means or limited space to work in.

Then the very system which is forcing the Pressman to work *anonymously* and *unrecognised* is against the best work.

There are moments of crisis when success is often bound up with prompt and kind co-operation shown by officials and others, and who are more likely to command these advantages than he who day after day comes into contact (as a studio worker) with people of authority and influence in his district? He has a much greater chance of making his personality tell when it is most wanted.

My professional friends will so well understand this that I almost apologise for stating it. The fact is, all "studio" men are "Press" men at times. It has always been a part of their business. In the 30 years of life in this my adopted city I have always striven to keep a photographic record, not merely of men and women, but of interesting *events*.

There are few occasions when local history has been in the making when the cameras of Regent House have not been busy, and any modest claim I may have to remembrance by citizens of future generations will rest, not on countless thousands of studio portraits, but on keeping careful records and writing the history of the air raids on Hull during the great war.

But if it is to be said that the studio worker is a pirate on the Press photographers' domain, what about the activities of certain ultra-modern snapshotters with whom we are continually becoming acquainted at weddings and other social functions! How often is the professional, who has been engaged by the family, annoyed by the sudden irruption of Pressmen, who, under the excuse that they represent this or that local paper, ignore the fact that they are uninvited, and proceed in the most ill-mannered way to jeopardise the success of the whole grouping by distracting interference. The public begins to recognise what the game means, and that it is a deliberate attempt to oust by cheapness and unfinished work the better but necessarily more expensive portraiture of the established professional.

Is this genuine Press photography? Of course it is not, and the only way to meet it is by giving the local paper a print to reproduce without fee, but with acknowledgment, and arranging previously with one's clients a fee for attendance and so many copies. An editor almost invariably chooses professional work, and sitters, especially the ladies, show a rooted objection to the hard sun-bathed results of the Press worker out of his proper element.

I am sorry I have taken so much space, but when a Press photographer goes out of his way to conjure up imaginary affronts and injuries it seems the time has arrived to present the other side, as it appears to a man who is "essentially a studio worker and a portraitist."—I am yours, etc.,

T. C. TURNER

Regent House, Anlaby Road, Hull.
September 19.

To the Editors,

Gentlemen,—I find that the letter *re* above, signed by Mr. Harness, Mr. Watson and myself, contains the following statement: "We were unquestionably the first on the scene, and secured the best pictures," etc., etc. The correct and intended rendering is: Two of us were unquestionably the first on the scene, and collectively we secured the best pictures, etc., etc.

I have never intentionally claimed that I was there before Mr. Turner. For this mistake (which in the haste of composing the letter went unchecked) I am personally very sorry, and beg Mr. Turner to accept my sincere apology as regards that regrettable mistake.

I enclose a few of my own photographs of the wreck, numbered in the order in which they were taken. They show the complete alteration in appearance that occurred during the half hour I was present. I make no claim that these are the first photographs taken, but they do prove that other photographers were there before the wreck broke up into fantastic shapes. Is there, may I ask, a complete and very striking difference as regards the position of the wreck between No. 2 of mine and the one taken by Mr. Turner?—Yours truly,

F. OVERTON.

85, Prospect Street, Hull.
September 17.

PLATES v. FILM.

To the Editors

Gentlemen,—Would it not be possible to turn this somewhat acrimonious correspondence into a useful and illuminating debate on the relative merits of plates and films? That, after all, is, or should be, the chief interest of the present discussion to most photographers. I would suggest two simple rules that should be strictly observed:—

1. A clear statement to be given by the writer of the length of his personal experience of the product he discusses.

2. An absolute avoidance of personalities, innendoes, and prophecies of all kinds.

Under Rule 1 Mr. Mallinson's letter in your last issue would have been barred, for he fails to state his qualifications as a judge of portrait film. Indeed, his remarks on working it seem to point to his never having got beyond the first preliminary trials, for most of the drawbacks he names are easily avoided by those who are really familiar with the film. And even if a careless worker succeeds in getting scratches on the back, he has a very big compensation, as any portraitist will tell him, in possessing the two surfaces for retouching.

Under Rule 2 we should have been spared Mr. Mallinson's droll confidences as to what he imagines Messrs. Kodak are up to, and his letter would not have lost the sympathy of readers.

I have used portrait film in Switzerland for the last four seasons (summer and winter) on most difficult lightings, often ranging from dark green foregrounds to snow-capped distant mountains, and in portrait work at home, and know from experience that the quality is exceptional owing to its absolute non-halation. There is no doubt about its convenience; one can develop half a dozen at once in the dark-room, or even in the hotel bedroom, as simple a performance as toning prints, pin them up to dry, and they store in a very small space and are unbreakable.

But their primary claim is for quality. So long as the sun is not actually shining in the lens, there is no effect, indoors or out, be it ever so daring, that they are not equal to, and for this same quality I would sacrifice all the minor advantages if it were necessary, for nothing but the best is worth carrying so far afield as the Swiss mountains.—Yours truly,

WILL CADBY

Borough Green, Kent.
Sept. 14.

To the Editors.

Gentlemen,—Since we commenced to use the Eastman portrait film, in April, 1914, we have always recognised that it is a product of sterling quality, and it has proved itself, in our hands, far superior to the plate for every class of work in studio and outdoor.

When using film one has the satisfaction of knowing that, however difficult the lighting, halation is non-existent, also it is much preferred by our retouchers to the plate, because of the extra amount of work that can be put on it with ease.

We have never had any trouble with markings of any description, and for filing purposes it is ideal.

Sometime ago we installed a set of Eastman tanks, with hangers, etc., and we found that this system proved itself most useful for the development of large batches of film negatives, and also the cost of developer, and time was reduced by at least 50 per cent.

Also good negatives are produced with ease and certainty.

We feel sure, however, that when one is taking a progressive step, conservatism should be put on one side, and the product tested on its merits.

If this is done in the case of the Eastman film, one cannot help but be delighted with the results, as, speaking personally, we really cannot see any disadvantages, but heaps of advantages in the use of this product of progress.

We are praising the film on its merits, and not because we are anyway interested in Kodak, Ltd.—Faithfully yours,

K. AND S. DARBY.

Canton Studios, New Street, West Bromwich.
September 14.

To the Editors.

Gentlemen,—Old combative times are recalled by reading the correspondence in your last issue on "films *versus* plates," and the policy of the Kodak Co., not by the particular subject, but by the spirit of controversy aroused. True, Mr. Harold Baker and others weigh pros and cons in impartial and helpful manner, but obvious special pleading is resorted to by one or two, and partisanship is evident.

Now for many a long year I have been interested in the printing quality of negatives, and many thousands from foremost studios in town and country have passed through my hands. I see consistently mediocre work turned out by some firms on the "portrait" film (still worse on plates), and note on rare occasions violent halation, or possibly "irradiation" alluded to by Mr. W. E. Debenham. On the other hand, work of the very finest class is consistently achieved by others on the film.

Personally, I believe that in many cases halation is the primary cause of loss of quality when it occurs, and with the films the operator not highly skilled is largely protected against himself, and, therefore, the production of good negatives is rendered easier. On the other hand, it is only just to say that the studio I should place easily first for turning out negatives of superb

quality with the greatest regularity employs ultra-fast dry-plates. Posing and lighting are right, exposure is correct, and development is stopped at just the right point for the printing process in view. In fact, skilled craftsmanship from start to finish. I emphatically assert that not one out of the very large number of film negatives I have seen has *beaten* the best of these dry-plate negatives for beautiful printing quality, though many a film negative has equalled them.

Not infrequently the "portrait" film is contrasted with an emulsion on glass of far higher speed, which is hardly fair. Apparently the English dry-plates makers have concentrated on the production of a plate combining the maximum of speed with a long range of gentle gradation, and admirably they have succeeded, but the ultra-fast brand remains a more delicate tool to work with than a film or plate coated with a slower emulsion. Mr. Debenham may "see no reason why an emulsion should be slower on a film than on a plate." Nor do I, but there may be a good and sufficient reason for not coating celluloid with an emulsion of extreme rapidity. Certainly there appears to be no doubt that the Kodak portrait film, although of ample rapidity to meet most requirements, does not attain the speed furnished by modern ultra-fast dry-plates.

In conclusion, I may add that unhappily I have not the faintest commercial interest in the manufacture of either plates or films, but admit a bias in favour of the film for occasional work. This does not justify depreciation of the dry-plate, which would be both silly and fatuous.—Yours truly,

"FAIR PLAY."

To the Editors.

Gentlemen,—I have read the letters, *re* above, with interest. We all know that an ounce of practice is worth a pound of theory, may I be allowed to state some of the advantages of films from my own practical use.

I have used them ever since Messrs. Kodak brought them out, and the advantages I have found over plates are as follows:—

1st, economy.—I can develop, and have developed, 24 flat films, ½-plate size, in a 10 x 8 dish at a cost of 3d. for the 24, including fixing, and every one a perfect negative.

2nd, rapidity.—I took a wedding group the other day in a very dull light; in fact, it was raining; stopped my lens to *f*/16 and gave 1 second exposure (as there were some tiny bridesmaids in it). Result, a negative full of detail and most brilliant.

3rd, portability.—12 films can be sent by post to be retouched at a cost of 4d.; 12 plates would cost over 1s. Again, 6 slides loaded with 12 plates weigh 7¼ lbs.; 6 slides loaded with 12 flat films weigh not quite 6 lbs. only, a great boon if you are going any distance, for weight tells.

I do not hold any brief for Messrs. Kodak, neither am I a shareholder (wish I was), but I think honour should be given where honour is due. One of their kind and courteous gentlemen who has the bad luck to have to call upon me showed me the other day a marvellous slide made to take plates or films. As soon as I can save up enough coppers in these hard times I am going to have 12 of those slides.

Again, how about the developing and printing of films for the amateur, which we do as a side-line. Don't we owe Messrs. Kodak something for that?—Yours faithfully,

W. ADAMS.

The Studio, Witney, Oxon.

To the Editors.

Gentlemen,—With reference to use of films, I have found the chrome-alum in fixing bath recommended by Messrs. Kodak, Ltd., exceedingly good for hardening the surface, while for varnish I think there is nothing better than celluloid. This is easily and economically made by dissolving scraps of film in amyl acetate until of the consistency of syrup. It should then be strained through fine net, and can be applied with a pledget of cotton wool, forming a very efficient protection from damp.

With those films having the bare celluloid on one side, careful application is required to the gelatine side only.—Yours faithfully,

F. S. WELLS,
Works Manager, The Doncaster Rotophoto Co., Ltd.

Doncaster.
September 16.

SYSTEMATIC BROMIDE PRINTING.

To the Editors.

Gentlemen,—It has been interesting to me to read what Dr. Glover has to say on bromide printing; also the letters of Mr. Baker and Mr. Hall. Dr. Glover's system, while no doubt excellent in itself, I consider unsuitable for a busy printer, but Mr. Baker and Mr. Hall seem to have been working on similar lines to myself.

In the early days of the war I, in common with most photographers, was troubled with the lack of competent bromide printers. I had several men who were supposed to be printers, but who, in practice, never managed to get a dozen prints of an order alike. To overcome this, I tried the following system:—3½ minutes was adopted as a standard time of development, using amidol, the temperature of the developer being raised in cold weather by a hot-water jacket, and kept to summer level. A trial print was made and developed for this standard time. If correct, any number of identical prints could be made by giving the same exposure. If too dark or too light, an extra piece of tissue paper was added to or taken from the printing box, or if the error was very slight, the exposure was altered ½ a second or 1 second. I arranged the light for a standard exposure of about 5 seconds, it being found that 4, 4½, 5, 5½, and 6 seconds covered practically every negative without altering the tissue paper. Nothing was left to guesswork; the thermometer was used for the developer temperature and the clock for exposure and development. By adhering strictly to this system, a youth who knew practically nothing about bromide printing was able to turn out remarkably good and regular batches of prints. A system of this sort immensely reduces the fatigue of a day's printing, so much of the personal element of judgment being obviated.—Yours faithfully,

GEO. WILKINSON.

849, High Road, Leytonstone, E.11.

To the Editors.

Gentlemen,—I am glad that the letters on bromide-printing have induced Dr. Glover to give us more information, as I am sure nothing but good can arise from a serious discussion of the subject, especially if others will give us the benefit of their experience. But I wish Dr. Glover had made experiments with other developers besides amidol, because excellent as that developer is, I do not think it is used to so great an extent as metol-hydroquinone by professional photographers. I may be wrong in this assumption, but I cannot call to mind any of my professional friends who are using it. I find that it generally needs a stronger negative than other developers, and often turn to it when a negative of more than usual hardness has to be printed. Its great virtue, to my mind, is that it will give almost the same sepia colour, when greatly varying exposures and prolonged development have been given, but the colour it gives is usually colder than I like, and there is always the objection that it so soon becomes exhausted.

In recommending the three-minute minimum of development, I, perhaps, over-emphasised the importance of the time mentioned. What I should have said was that I find three minutes a valuable standard, allowing for all the variations in paper, negative, temperature, etc., and that each should find for himself the standard average time which produces the result desired. This method is not as scientific as Dr. Glover's, but I think it is better than having no system of timing, and easier for everyday work than Dr. Glover's method, which, I am afraid, we should have difficulty in persuading assistants to adopt.

I do not think it is possible to handle a large number of prints successfully with a shorter time of development than three minutes.

As to the colour of the print when toned, I think we are both agreed that long or full exposure, and short development gives warmer colours, especially when using any other developer than amidol. But I think that Dr. Glover's claim that increased time of development will compensate for decreased exposure, and produce a similar is not confirmed by my own experience. It may be possible to do this, but within a very limited range.

Dr. Glover's two stories seem to me arguments against the success of his system. I am writing without being able to refer to his article, but if my memory is correct he claims that his method is more reliable than inspection, but if his claim that prolonged development compensated for reduced exposure is right, then in these

two cases where the exposure was accidently reduced, prolonged development, which would have been suggested by inspection, should have put matters right.

I hope Dr. Glover will continue his experiments with other developers, and give us the benefit of his results.

I am afraid many of us are like the tailor in Punch, who, when a customer complained of the fit of his clothes said: "I must ask you bear in mind, sir, the tailoring is not yet reduced to the level of an exact science." A good many photographers are inclined to say the same of photography, but I am sure we are greatly helped when investigators like Dr. Glover bring some exact science to bear on the problems that confront us in our daily work.—Yours truly, HAROLD BAKER.

"THE DEATH" AT THE SALON.

To the Editors.

Gentlemen,—In criticising my picture "The Death" (No. 55) in his review, in your issue of September 16, of the present Exhibition of the London Salon of Photography, Mr. Tilney appears to have taken the two figures to be human beings when he writes that the dying figure is posed and the lady behind looks more like a monumental effigy. I should like to inform Mr. Tilney that the subject is the Shelley Monument in Christchurch Priory.—Yours truly, AUBREY G. RAYMOND.

32, Eastland Road, Neath, South Wales.
September 19.

Answers to Correspondents.

In accordance with our present practice a relatively small space is allotted in each issue to replies to correspondents.

We will answer by post if stamped and addressed envelope is enclosed for reply, 5-cent International Coupon, from readers abroad.

Queries to be answered in the Friday's "Journal" must reach us not later than Tuesday (posted Monday), and should be addressed to the Editors.

C. G. ROSENBERG.—We are sorry we cannot give you any information regarding developers which give a finer grain in the negatives than the original grain. So far as we know this property is not possessed by developers, which, in other respects are of practical value in the making of negatives.

T. H. LEGGE.—With a properly restrained developer you ought to have no difficulty in getting white margins when using a mask on the enlarging easel. In any event could you not give the enlargement a quick rub over with weak iodine cyanide reducer on cotton wool, which would remove any slight veil of silver deposit?

J. LADE.—(1) Best to develop for only about a minute, fix, wash thoroughly, and then intensify with the uranium intensifier. (2) Rather out of our province. We think the pads are simply made of cotton fabric with cotton padding inside. (3) It is the best pattern you can get. (4) No, you can use a lens at a larger stop than when copying on a reduced scale.

J. S.—It is not beyond the capacity of a careful worker to albumenise and sensitise paper. The very fullest instructions (and these are necessary) are contained in the manual, "Photographic and Photo-Mechanical Printing Processes," by W. K. Burton, which you can buy from Messrs. Foyle, 121-123, Charing Cross Road, London, W.C.2, for a shilling or two.

F. B.—Even supposing that copyright still exists in the picture (we think it is quite possible that copyright has expired) there would not be any infringement in your making a photograph in which a child of similar appearance is posed in the manner of the painting. The law is rather peculiar on this point, but we think you may take it that you are practically secure in considering that the owners of the picture would not think you were infringing their copyright.

F. W.—(1) The only lamp is that of the Blanchard Lamp Co., 151, Farringdon Road, London, E.C.1. It burns ordinary paraffin and costs, or used to cost, about £10 to £15. (2) Billcliff's Camera Works, Richmond Street, Boundary Lane, Manchester. (3) The London agent of Messrs. Lumière is Mr. T. K. Grant, 89, Great Russell Street, London, W.C.1, by whom all the Lumière goods are supplied in this country. (4) Messrs. Fallowfield, 146, Charing Cross Road, London, W.C.2, make a specialty of mounts and other miscellaneous goods for stickyback portraiture.

A. W. S.—Half-watt lamps will answer perfectly either as a supplement to daylight or for working alone at night. For the former purpose two 1,000 c.p. lamps placed near the ceiling about 7 ft. from the background in front of the sitter should be enough. For night work you would require three more lamps of the same power arranged in a curve commencing from a point opposite one edge of the background, and continuing round to meet the two used with daylight. The front lamps should be about 8 ft. from the floor, the side ones may be rather lower, say 6 ft. You must consult your electrician as to the meter and wiring.

MARCUS SHAW.—It is rather uncommon for single blisters to appear on prints after their being in the wash water for as long as half an hour. The fact suggests that the water may impinge in a fine stream on certain prints, or perhaps prints may have been "kinked" in places in turning them over. The means for prevention, apart from those suggested by what we have just said, are to keep all solutions at the same temperature; and you might also transfer prints to a fixing bath of half or quarter strength instead of to plain water when they have been fully fixed in the hypo of the ordinary working strength. Have you tried whether the use of a hardening-fixing bath, made up with alum, sulphite, hypo, and citric acid avoids the defect? It is possible that it may do so.

W. A.—(1) There is not any substantial advantage in using an $f/4$ aperture over one of, say, $f/6$ or $f/8$, so far as avoidance of retouching is concerned. Using a plate of fine grain, it should be quite practicable to make negatives which would give post-card enlargements practically indistinguishable from prints from direct negatives, but an aperture of $f/4$ is not necessary for this purpose, but, in fact, has rather a contrary influence. We should say $f/6$ is about a useful aperture for this purpose. (2) Film-packs require an adapter in which the pack itself is held in order that the successive paper separators may be drawn off, and so expose one section of film after another. The pack is complete as purchased, consisting of a stout card casing strengthened with thin metal. Having the adapter in which to hold it at the back of the camera, no other accessory is needed. (3) With all the actinometers that we have tried there is a slight difference in colour between the tint and the darkened sensitive paper, but it is not a difficult matter to judge, with sufficient nearness, a match of "depth" apart from any slight difference in colour.

SUMMARY

In a further series of notes on the pictorial exhibits in the exhibition of the Royal Photographic Society, Mr. F. C. Tilney deals particularly with the landscapes. (P. 579.)

Mr. W. S. Davis, in our American contemporary "Camera," gives some useful tables for obtaining the maximum sharpness of objects at different distances from the camera by proper selection of the marking on the focussing scale in conjunction with the lens stop. (P. 583.)

In the further chapter on the speed of a lens, the causes of falling off of illumination towards the margins of the plate are considered, namely, that which takes place regularly with every lens, and that which depends upon the degree of cut-off by the lens mount. Figures are quoted showing the extent to which illumination falls off in the case of wide angle lenses. Absorption and reflection of light by the glasses of the lens are further factors affecting speed which almost always are neglected. (P. 580.)

A correspondent, Mr. Louis Nell, raises the question of the greater rapidity of small lenses compared with those of the same f/No., but of longer focus. (P. 589.)

We refer to this question in a paragraph on page 577.

In a leading article we give two rules which are of frequent usefulness, namely, those for finding the distance between object and ground glass when enlarging or reducing upon any scale with a lens of given focal length, and also the possible degree of enlargement or reduction within a prescribed distance between image and object. (P. 578).

Destruction of a wet gelatine film by insects is an annoying mishap which occasionally occurs and against which the only effective safeguard is the use of a drying chamber covered with muslin or other open fabric. (P. 578.)

Adjustment of the distance of the light, or means for using "dimming" screens, should be a feature of the bromide printing box. (P. 578.)

A short communication to the "Chemical News" by Mr. J. G. F. Druce states that the composition of the black substance which is formed when mercurous chloride is acted on by ammonia. (P. 584.)

As has, however, been shown by Mr. Chapman Jones, the product formed when ammonia is used for darkening the image (of mercurous chloride) in the mercury-ammonia intensification process is not of this definite composition. (P. 578.)

In further discussion of the respective merits of plates and film, correspondents lay stress on the relative speeds of emulsion on glass and film and on the storage of film negatives. (P. 590.)

In accordance with the discontinuance of summer time, clocks will require to be put back one hour during the night of Sunday-Monday next. (P. 588.)

An absurd prosecution under the Business Names Act was recently dismissed by a London magistrate. (P. 588.)

EX CATHEDRA.

The 1922 Almanac. The 1922 edition of the British Journal Photographic Almanac is now in an advanced stage of preparation as regards both its text and advertisement pages. All being well, it is hoped to publish it on or about December 1. We have issued application forms to secretaries of photographic societies and to photographic firms, requesting correction of the particulars which appear in the respective directories of societies and the photographic trade. We shall be very glad if those to whom these applications have come, and who have not yet returned them, will do so without further delay. Unfortunately, in compilations of this kind, it is the last comers who fix the time at which a section of the Almanac can be printed. Naturally, there is a limit beyond which we cannot wait, whether particulars are forthcoming or not. Apparently, in the case of societies delay chiefly arises in consequence of a change of secretary of which we have not become aware. In such cases, we send to the previous secretary, but it seems not to be the invariable rule that the ex-officer forwards the application promptly to his successor. We make this comment in the hope that those to whom it applies will take the hint. A second application has just been made to secretaries and firms who have not answered the first. The third, and last, will be made in a week's time.

* * *

The Speed of Small Lenses. The letter by Mr. Louis Nell, which appears on another page, raises a point which undoubtedly is deserving of more attention than it commonly receives. As set forth in the article which appeared in our issue of September 16, the working aperture or number of a lens is rated solely according to the proportion which the focal length bears to the diameter of the largest stop. Yet, after all, this is not the only determining factor, since the number of separate glasses in a lens, and their colour and thickness, considerably affect the brightness or intensity of the image which is formed on the ground glass. We refer briefly to this subject in the concluding paragraph of the article which appears this week. We know that some very experienced and methodical users of small cameras, *e.g.*, of vest-pocket size, regularly make a great allowance for the extra speed of the small 3-inch lens which is usually fitted. In one case that we know, an expert photographer adopts one-fifth the time of exposure compared with that which he would consider correct when using a lens of, say, 6 or more inches focal length. Fineness of definition no doubt enters also into this question, and, considering the present widespread use of very small lenses and cameras, it certainly seems that there would be a practical advantage to the user if the extra rapidity of these small lenses could be more definitely established on theoretical grounds or as the result of experimental measurements. Perhaps some of the lens makers have data in their possession which bear on this point.

Mercury-Ammonia Intensifier. The note by Mr. J. G. F. Druce, which we reprint on another page from the "Chemical News," relates to the process of mercury intensification in which the bleached image is darkened with a solution of ammonia. From analysis, Mr. Druce finds that the composition of the dark substance corresponds with the formula NH_2Hg_2Cl, which is that generally adopted by chemists. The note is of interest as tending to show that the black substance, when produced in this way by the action of ammonia solution on mercurous chloride, is a definite compound. This, however, is contrary to what has been found by Mr. Chapman Jones, and later by Leteur, under the somewhat different conditions which prevail in the use of the mercury intensifier. Here the ammonia solution acts not on mercurous chloride alone, but on a mixture of silver chloride and mercurous chloride existing in gelatine. Mr. Chapman Jones's experiments of some years ago clearly showed that ammonia, used in the strengths which are commonly employed for darkening the bleached image, dissolves mercury irregularly from the dark substance, a property which accounts for the somewhat erratic behaviour of this intensifier upon the scale of tones in a negative.

* * *

A Printing Hint. To secure even quality in bromide printing it is a good plan to sort out the negatives into batches of as nearly equal density as possible, and if this can be done by daylight so much the better, as with pyro development there are often variations in colour which will cause a comparatively thin negative to take as long as a fairly vigorous-looking one. As Dr. Glover points out, the usual practice in bromide printing is to over-expose and to stop the development at a comparatively early stage. This is open to two serious objections, one being that the gradation of the negative is less truly rendered, and the other that such prints are unsatisfactory in colour when toned. A fault in many printing boxes is a lack of means for controlling the light, involving, with thin negatives, a very short exposure which cannot be repeated with any degree of accuracy. Most boxes are too shallow to allow of any appreciable variation of light being obtained by altering the distance of the lamps, and in such cases it is necessary to use translucent screens as "dimmers." These should be carefully tested and marked to indicate the actual increase of exposure needed with each.

* * *

Insects and Gelatine. It is, perhaps, not well known that the ordinary house spider has a distinct partiality for the wet gelatine films of plates set up to dry, in illustration of which an instance from our own experience may be given. A number of plates exposed upon a holiday had been developed, fixed, washed, and set up to dry upon a shelf. In the morning they were taken down, and upon the bottom edges of several of the negatives the films had been eaten away to the glass in a series of semi-circular holes, the largest being about an eighth of an inch in diameter. The plates were not of any particular value, though, if they had been, the probability is that the spiders would not have refrained from their meal. While on the subject, we may point out that spiders are not the only form of lower insect life that appreciates a square meal of gelatine. We have known gnats perish in the attempt to obtain sustenance from a drying negative. Nor is this entirely confined to the insect species. A friend of ours on holiday in the country at a time when water was not plentiful, and also with a view to saving the labour of drawing the washing water from the well, conceived the idea of putting his films in their washing tank in an adjacent brook. When, a short time after, he went to see how they were getting on, he found that some tadpoles had been faring sumptuously upon his gelatine emulsion. Thereafter, he was careful to tie a piece of butter muslin entirely over the top of the washing tank, in order to exclude these unwelcome intruders.

APPROXIMATE FORMULÆ FOR CERTAIN REDUCING AND ENLARGEMENT CALCULATIONS.

A FEW months ago, in our issue of July 1, 1921, p. 382, we wrote some notes explanatory of a very simple formula which may be used in order to find the focal length of lens which is the longest which can be used in a studio of given size for any particular kind of portrait, from full-size heads to carte-de-visite full lengths. As was pointed out, the chief factor in calculations of this kind is the degree of reduction; that is to say, the size of the image relatively to that of the object. In ordinary studio work the greatest degree of reduction, which is commonly employed, is in taking a full-length carte-de-visite. If the figure on the print measures 3 inches, its proportion to the average height of a person is one-twenty-third, or, as is usually said, the "reduction figure" is 23. This being understood, the formula for the longest focal length which can be used is simply the distance between the sitter and the ground glass of the camera divided by a number which is 2 greater than the reduction figure.

In giving examples of the use of this method, we did not point out that the formula serves equally well for ascertaining the dimension of a studio which is required for various descriptions of work with a given focal length of lens, and also for ascertaining the types of work (degrees of reduction) which can be done in a given space with a lens of given focal length. As several correspondents have recently inquired for a simple rule which applies in these conditions, it may be of service to others to indicate the variation of the rule which, in our previous article, was put forward only for the particular purpose of ascertaining focal length.

It must be pointed out that these rules are not absolutely exact, because they leave out of account the extra camera extension which is required when photographing objects which are nearer than the "infinity" corresponding with a camera extension equal to the focal length of the lens. But this distance is a very small one in all cases of enlargement or reduction greater than about 6 times, since it is then less than one-sixth of the focal length. Nevertheless, it is necessary to point out that for degrees of enlargement or reduction between about 6 and same size the rule is not sufficiently exact, even for the approximate calculations which usually are sufficient in the taking of studio portraits or the making of enlargements.

First, as regards the length of a studio which is necessary for various types of portrait with a given "focus" of lens. If we call the degree of reduction in size R, *e.g.*, 23 when making carte-de-visite full-length portraits, and D the distance which requires to b provided between the sitter and the ground glass, then

$$D = (R+2) \times f.$$

f representing the focal length of the lens.

In words, to find the required distance add 2 to the reduction figure and multiply by the focal length. The result is the required distance in inches. For example, if it is required to make full-length carte-de-visite portraits with a 10-inch lens, what length of studio is necessary? Here R (the reduction figure) is equal to 23. Adding 2

and multiplying by 10, we get 250 inches, equal to (practically) 21 ft. Inasmuch as it is necessary to have some space behind the sitter and also behind the camera, it is usual to add about 5 ft., so that the minimum length of studio for convenient working is 26 ft.

To turn now to the other form of the calculation, ummely, to find the reduction figure which is possible when enlarging or reducing within a given space, when using a given focal length of lens. Using the same symbols as before the formula for this reduction figure is

$$R = \frac{D - 2f}{f}$$

In words, subtract twice the focal length from the available distance and divide by the focal length. The result is the number of times of enlargement or reduction which is possible under the conditions.

An example of both enlarging and reducing will serve to show how this formula is used. Suppose we have a distance of 5 ft. available between the negative and the easel in a vertical enlarger fitted with an 8-inch lens. What is the maximum degree of enlargement which can be done? Following the rule, we subtract twice the focal length (16 inches) from the available distance (60 inches). This leaves 44 inches. Dividing by 8, we get 5½, which is the maximum number of times of enlargement which can be done under these conditions.

To take another example from the studio. In a studio of overall length of 27 ft., what is the maximum degree of reduction which can be obtained with a 12-inch lens? If we wish to allow 5 ft. for the spaces behind the sitter and behind the camera, we must first subtract 5 from the overall length, leaving 22. Then, according to the rule, subtract twice the focal length (24 inches) from this distance (264 inches), leaving 240 inches. Divide by the focal length, which gives 20 as the maximum degree of reduction. It will thus be seen that the studio space, while ample for cabinet full lengths, which require a reduction figure of 13, is not quite enough for carte-de-visite full lengths, requiring a reduction figure of 23. As the first rule shows, for reduction to this latter smaller size the distance between the ground glass and the sitter must be 25 ft. with a 12-inch lens, so that we must either make do with a lesser space behind the sitter or the camera, or use a lens of somewhat shorter focal length.

THE ROYAL PHOTOGRAPHIC SOCIETY'S EXHIBITION.

The lectures to be delivered during the current week at the exhibition of the Royal Photographic Society include a discourse on the making of portraits by Mr. C. P. Crowther on Tuesday next, October 4. On Friday, October 7, Mr. E. W. Harvey Piper will lecture on Chartres Cathedral. The lecture to-night, Friday, September 30, is "Wonderlands of the Western World," by Mr. J. Dudley Johnston, whose lantern slides invariably are works of artistry which the lantern-slide maker cannot too often have the opportunity of seeing. All these lectures begin at 8 o'clock, and, like the exhibition itself, are open free to the public.

The notices of the Exhibition conclude with the following further review of the pictorial section (landscape prints) by Mr. F. C. Tilney.

LANDSCAPE IN THE PICTORIAL SECTION.

As already stated, the really good landscapes are more numerous than the really good figure subjects, and they are by R.P.S. men at home, not abroad. On the whole, I think that Bertram Cox and T. H. B. Scott this year hit up the record for Russell Square. Mr. Cox's view of the Tower Bridge, called "The River" (71), is entirely free from those little misfortunes in tone-values and textures which hand-controlled works so frequently show. He has long since got past the rubicon of composition—that is the first thing that photographers set out to achieve—he has reached the highly advanced stage of knowing and seeing the more elusive truths that escape all but the artist schooled by observation. His Tower Bridge stands free in the air, it is not in front of one part of the sky and behind another part—the fate of the average bromoiled tower. Light glints upon it, but does not drag it out of its proper plane. In fact, the great beauty of this print is far more that of aerial perspective which is convincingly right than those of design which is the fetish of one school of photographers. Yet the design is scarcely beaten in this show. Nature again, though with no more poetry, speaks in his "Evening on the Arun" (71); a sunny expanse, broad and simple in its masses of light and shade. "In Arundel Park" (32) the design is imposed by the lines of a little fold in the hills. It is perhaps a thought too regularly balanced for a free and natural design. I feel that the little figures on the left constitute a dark spot that is too isolated to be of any help to the composition. Another valley design comes from T. H. B. Scott. Across a little dip in the fields depicted in "Lengthening Shadows" (76), the shadows from some trees are cast by the low sun. They are foreshortened to a narrow line which follows the contours of the ground. Beyond is a fine expanse. A rich mellow quality distinguishes this, as all other prints by Mr. Scott. Indeed, I am not sure that the richness of quality in his "Chalk Pits" (80) has not been the occasion of some sacrifice in other directions. The lateness of the effect does not tally with the amount of detail which, though drowned in tone, is not eliminated as it would be naturally. In his "Arundel" (86) a picturesque group of trees saves a fine thing from being very nearly an unfortunate composition, the chief line running down and out rather obviously.

A remarkable piece of truth of tone comes from F. E. Cederberg called "Vinteraftan" (18). It shows a Swedish winter afternoon with the lingering luminosity of a dark northern sky. This gleams upon the snowy roofs of a quiet town. In the distance is a hall or church lit up inside, and here is the bad spot in an otherwise charmingly true effect—the windows shriek of retouching. Other good examples of good tone effects are "The King's Arms" (54), by Hugo van Wadenoyen, Junr., a plucky scheme of side illumination by sunlight; the even better "Shadows on Whitewash" (73), by the same worker; "Lewes" (53), with its simple masses of even tone, by H. L. Wainwright, and "Sunset at Hradchui, Praha" (84), by J. J. Happ, which is a valiant attempt to seize by tone the charms of the western evening sky. The success of a work of this sort is in the exact ratio of the response of a spectator who knows enough of Nature to see what it implies: to the unobservant person it would be a dull thing. The "Sun Splash" (44) of J. A. Lomax would likewise be "cavaire to the general," in spite of its remarkable luminosity.

Other landscapes that deserve special commendation are H. Ruddick's "Welsh Landscape" (28), a magnificent prospect, with perfect recession. F. O. Libby's "The City—New York" (50), which is not in the habitual blue tint, and, therefore, more grateful to the eye than usual; "Evening Sunlight, Venice" (78), by Louis J. Steele; Alex. Keighley's "Court-

yard" (79), a nice composition, with sun streaks falling across floor and walls; and "The Lifeboat, Criccieth" (91), a dark and dramatic seascape, by F. K. Glazebrook. Capt. Alf. G. Buckham sends further examples of his excellent cloud studies, or rather cloud landscapes, "A Coming Storm" (87), "Three Miles Above the Earth" (93); and "Finis Coronat Opus" (70), which, in the matter of gradation, is certainly his crowning work: a fine picture of sea and sky and an aeroplane. The newness and vigour of these works make them very refreshing. And so in a measure is Oscar Maurer's highly pictorial scene called "Forest Rangers in California" (106). But this is anything but new; it is like an old book-illustration, happily composed, with a fine relief of chiaroscuro, and in every way equipped with the attractiveness that charmed our aged parents before the photographic era. Pictorial charm is likewise strong in "Florence—the Old Bridge" (129), by H. Y. Summons. This holds a deal of literary interest of the romantic kind. "The Lake" (154), by F. O. Libby, has the romantic touch also, as well as the "big" feeling, which is the outstanding characteristic of Mr. Libby's work. And in the same category should be mentioned "A Canyon by the Sea" (158), by N. P. Moerdyke.

The notable figure works were by no means exhausted in my first notice of this exhibition, and it is necessary to direct attention to "The Heir" (11), by Charles Borup; a baby who is sitting up with a precocious air without the help of any supporting arms. I am disposed to think this a new sort of triumph in the photography of infants. Another notable work is "A Character Study" (21), by C. Pollard Crowther. It is a beautiful print, and only slightly spoilt for me by a kind of actor's excess of muscular mobility about the mouth. Madame Yevonde's pictorial portrait of a girl in a dressing-room putting on "The Ballet Shoe" (42) is a fine example of its kind. Ballet skirts are the motive of Marcus Adams's "Dancing Girl" (43) also; a pretty child standing before some dark curtains. The pose and lighting are remarkably happy. A similar subject is "The Ballet Dress" (7), by Mrs. K. Gash. Here the sitter is a young lady in her 'teens. The arrangement and general treatment of this print have much distinction. Geo. Turner has certainly not enhanced the attractiveness of his eminent sitter "Mark Hambourg" (13) by allowing him to wear the hideous goggles that are the present craze of all who lay claim to be anybody in particular. It only remains to mention the curious carved idol aspect of "The Rag-Picker" (48), by Maurice Beck—a combination of flatness and sharp modelling, the effect of which is produced by the inclusion of a white wall behind the figure. This forces a contrast that suppresses the tone of the sitter; but whether it is admirable or merely startling is a matter of individual taste.

Is it wise of the Society to encourage the sending in of little things such as one sees at an average local club's exhibition? Such works may be highly creditable and full of beauty; but they look their worst, not their best, upon walls that display fine imposing prints. The regulation area for all entries has much to commend it; for the senders who prepare prints on sumptuous lines are usually those who understand what pictorialism demands. If there must be a collection of little "gems" they might perhaps be on a screen by themselves; but even then they would be overlooked. F. C. Tilney.

THE SPEED OF A LENS.

[Of the sub-divisions of photographic optics, those which relate to the effect of the stop are of the greatest practical importance, and, fortunately, are those which permit of explanation of the first principles by the use of mathematical symbols or formulæ of the simplest kind. In the preceding chapter ("B.J.," September 16), was considered in this simple form the relation of the stop to the "speed" of the lens. It was first shown how the familiar F. No. is derived from the action of a lens and how the F. No. varies from its nominal value when the object is relatively near to the lens. Older systems of marking the stops of lenses were explained, and the concluding part of the article now deals with the two-fold cause of the falling-off of illumination towards the margins of the plate. It is hoped that an occasional article of this kind will contribute to a more exact understanding of familiar working facts and figures by those who are disinclined to include in their reading anything which they regard as "only theory."—Eds., "B.J."]

II.

Variation of Intensity of Lens Image over Field.

In the foregoing we have considered the image formed in or near the centre of the field of the lens. The intensity of the image, however, falls off towards the margins of the field; or, as is commonly said, the plate is not so well illuminated towards the edges.

This falling-off arises from two causes, one regular and applying equally to every lens, the other irregular and varying according to the particular form of the lens mounting. The latter cuts off the marginal rays to a greater or less degree. The reduction of intensity from these two causes together becomes considerable only with wide angle lenses, and even in the case of their use is less serious in its effect than might be supposed in consequence of the latitude of the plate.

Regular Reduction of Marginal Intensity of the Image.

The factors which enter into the regular diminution of the image were shown many years ago by R. H. Bow ("B. J.," 1866, April 6, p. 160), who arrived at the formula that if the brightness of the image on the axis is i, that at an angle Q to the axis (equivalent to an angle of view of 2Q) is

$$i \cos^4 Q.$$

If it is borne in mind that the cosine of an angle is simply the ratio of the base to the hypotenuse when that angle occurs in a right-angled triangle, the derivation of this formula will be easily followed. In the triangle A B C (fig. 4) the cosine of the angle Q is the ratio of BC to AB $\left(i.e., \frac{BC}{AB}\right)$.

For angles from 0 to 90°, representing angles of view up to 180°, the value of this cosine ratio ranges from 1 to 0—that is, through a series of fractions (*e.g.*, cosine 30° = .86; cosine

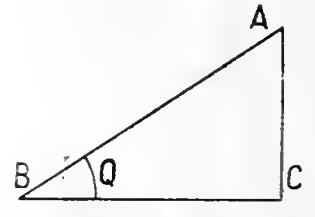

Fig. 4.—The cosine of an angle. The ratio of BC : AB is the cosine of the angle Q.

45° = .71; cosine 60° = .50), which gradually become smaller. Hence it is clear that the application of the formula yields much greater proportional reduction of intensity as rays reach the plate at a greater angle.

The three factors which cause a regular (*i.e.*, calculable) reduction of the brightness of image towards the margins of the field are shown in figs. 5 to 7.

(1) *Virtual Constriction of Aperture.*—The first relates solely to the diaphragm. In fig. 5 *aa*, *bb* represent the limiting rays of the cylindrical pencil which can pass through the diaphragm aperture *ab*. The intensity at the centre of the field is therefore proportional to the area of the aperture, *i.e.*, to $(ab)^2$.

But an oblique pencil *cc*, *dd*, of diameter equal to that of *aa*, *bb*, does not pass through the aperture, because this latter is presented to it at an angle, and, therefore, the effective passageway becomes virtually contracted to an ellipse having

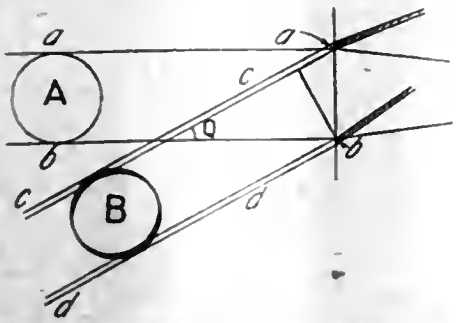

Fig. 5.—Reduced image-intensity through reduction of effective aperture of diaphragm for oblique pencil of rays.

one dimension equal to *ab* and the other smaller. This effect can be seen by holding a circular disc, such as a coin, level with the eye and gradually turning it on the line of sight: the circular area is seen to become elliptical. Part of the pencil is therefore cut off, as indicated by the shaded portion, but more correctly by the equivalent sections of the aperture for axial and oblique pencils shown at A and B.

Now it can be shown that if *s* is the *area* of the full circular aperture, that of the ellipse effective for a pencil making an angle of Q with axial rays is

$$s \times \text{cosine } Q.$$

Hence from this cause alone the intensity *i* of the axial image is reduced to *i* cosine Q when the rays make an angle Q with the lens axis.

(2) *Greater Focal Distance of Marginal Rays.*—The second factor is that the focus of marginal rays is at a greater distance from the diaphragm than that of the central pencil

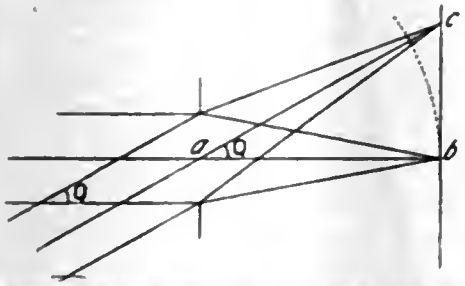

Fig. 6.—Reduced image-intensity through greater focal distance of marginal rays.

In fig. 6 the distance *ac* is greater than *ab*; and hence, according to the diminution of illumination inversely as the square of the distance from the source of light, the brightness of the image at *c* is less than that at *b* in the proportion of $\frac{(ab)^2}{(ac)^2}$.

But in the triangle *abc*, $\frac{ab}{ac}$ = cosine Q.

Therefore the ratio

$$\frac{(ab)^2}{(ac)^2} = \text{cosine}^2 \text{ Q}.$$

Thus, from the two causes of virtual aperture constriction and greater distance, the intensity of image at the angle Q becomes $i \times \text{cosine}^2$ Q.

(3) *Angling of Marginal Rays to Focal Plane.*—The third factor is that the marginal pencil does not fall perpendicularly upon the sensitive surface as does the central pencil. The surface on which it would fall perpendicularly is *RS* (fig. 7),

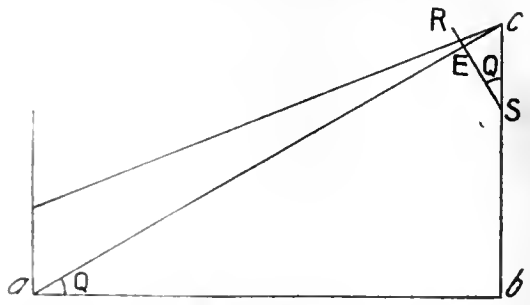

Fig. 7.—Reduced image-intensity through obliquity of marginal rays to image plane.

which is at an angle *c S R* to the sensitive surface. The area of each little bit of image (represented on an exaggerated scale by *ES*) which is received by the sensitive surface therefore becomes *c S*, and therefore the intensity of illumination is less than that produced by perpendicular central rays in the proportion *SE* : *cS*.

But $\frac{SE}{cS}$ = cosine of the angle *c S E*, which, from the drawing, is equal to Q. Hence, on account of the obliquity of the image-forming rays, the intensity of image is further reduced by the coefficient cosine Q.

From all three causes, therefore, the intensity at angle Q

$$= i \times \text{cosine}^4 \text{ Q}.$$

The magnitude of the reduction in the intensity of the image according to this formula at various angles of view is shown in fig. 8. The angles of view subtended by the diagonal of the plate are marked on the upper line of the diagram, the

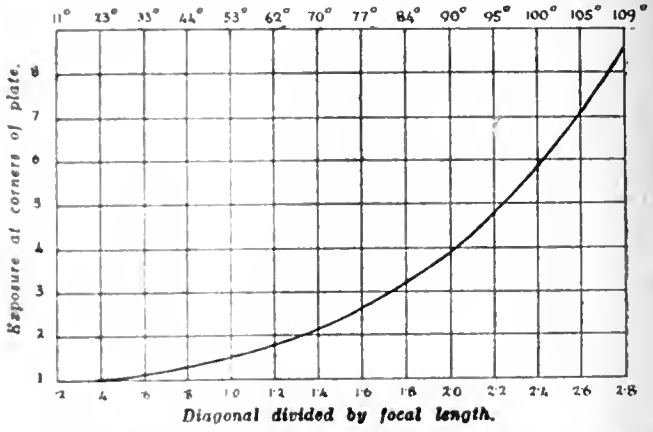

Fig. 8.—Diagram showing exposure required at edge of circular field compared with that at centre in accordance with cosine⁴ rule.

value in each case being, of course, double that of Q in the formula. The figures below the diagram are the ratios of diagonal of plate to focal length of lens corresponding with each angular value. The ordinates (upright) scale is marked in exposures, compared with an exposure of 1 on the axis. Thus, at an angle of view of 53°, corresponding with an 8-in. lens on 6½ × 4¾-in. plates, the exposure required in the extreme corner of the field is about 1½ times that in the centre. At an angle of 90°, corresponding with the use of a 4-in. lens on a 6½ × 4¾-in. plate, nearly four times the exposure in the centre is required.

It must be repeated, however, that the rule embodied in the curve holds good only when there is no obstruction of oblique rays by the lens-mount—that is, when the diaphragm aperture is clearly visible, though of elliptical shape, when viewed from the margin or corner of the field, as by turning back the focussing screen and applying the eye to the edge or angle of the space left by it.

Irregular Reduction of Marginal Intensity through Cut-off by Lens Mount.

The intensity of the image towards the margins of the field suffers an irregular reduction whenever the diaphragm aperture is of such size relatively to the dimensions of the lens mount that the oblique pencil of rays cannot pass through.

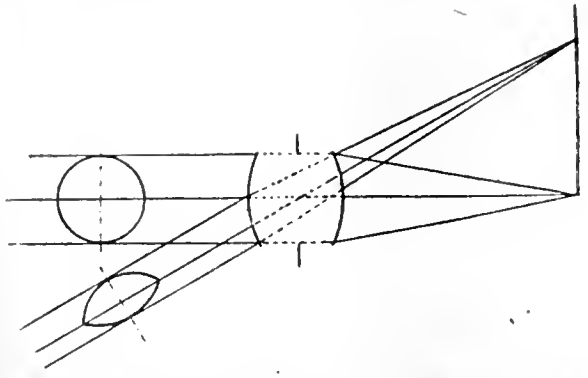

Fig. 9.—Constriction of marginal pencils through (1) cut-off of oblique rays by lens mount, and (2) reduced effective apertnre nf diaphragm.

This state of things is shown in fig. 9, where the transmissible pencil of rays is that in dotted lines, the aperture which is actually effective becoming contracted to the size and shape shown on the left.

This drawing serves as a reminder that in the case of lenses the mounting of which causes much cut-off, the actual diameter of the largest stop may be a very misleading indication of the "speed" of the lens a little way from the centre of the field. In fact, old lenses are occasionally met with in which the largest diaphragm aperture is larger than the front lens and with which, therefore, even the axial transmissible pencil of rays is smaller than the diaphragm aperture.

Reduction of marginal intensity from cut-off obviously occurs chiefly with lenses having a large relative aperture, more so in the older patterns of lenses than in anastigmats having their elements near to each other and the lens mounts correspondingly short. Many rapid rectilinear lenses will show cut-off at apertures larger than $f/16$, whereas an anastigmat may be free from it at apertures smaller than $f/8$. Sufficient stopping down of almost any lens eliminates the cut-off

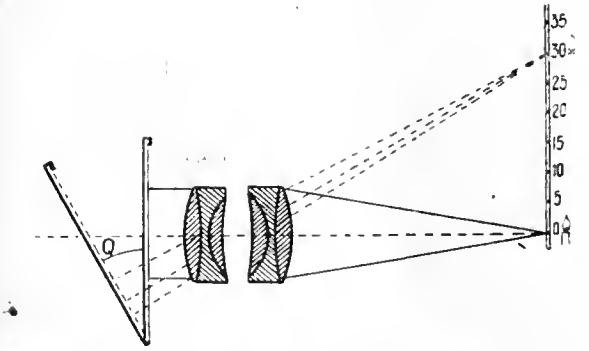

Fig. 10.—Measurement of effective diaphragm aperture (including cut-off by lens mount) for oblique rays.

effect, the image then undergoing reduction of intensity towards the margins according to the regular cosine[4] rule already considered.

While it is not possible to calculate the reduction of marginal intensity due to cut-off, the area of the constricted and deformed diaphragm aperture which is virtually effective for rays of any given obliquity can be measured, as suggested by W. Zschokke ("B. J.," 1912, October 25, pp. 823-827), and the angular image intensity computed by multiplying the area by cosine[3] Q (not cosine[4] Q, since the factor of diaphragm aperture is included in the experimental measurement). The method consists (fig. 10) in replacing the focussing screen by a metal plate pierced with fine apertures at distances from the centre of the field corresponding with 5°, 10° values of Q. *i.e.*, with angles of view of 10°, 20°, etc. The lens being focussed on infinity, rays from a light-source placed behind a given aperture in the plate are received on a surface placed perpendicularly to the emergent parallel pencil, and may be photographed on a piece of bromide paper placed there.

Figs. 11 and 12 show, on a reduced scale, the shapes and relative sizes of the contracted and distorted diaphragm apertures which are effective for rays of increasing degrees of obliquity, in the case of a lens at full aperture $f/6.8$ (fig. 11) and with the same lens at $f/15.5$ (fig. 12). It will be noticed that at full aperture the diaphragm begins to be cut-off at an angle of 15°, whereas at $f/15.5$ it remains effective at the full aperture up to an angle of 25°.

These angles correspond respectively with angles of view of 30° and 50°, equivalent to the use of lenses of 12 in. and 7 in. focal length on a $6\frac{1}{2} \times 4\frac{3}{4}$-in. plate. By measuring the areas of the constricted apertures and multiplying each by the

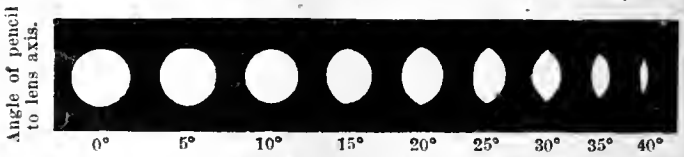

Fig. 11.—Effective diaphragm apertures (for oblique pencils) for double anastigmat at full aperture ($f/6.8$).

coefficient cosine[3] of the respective angle of obliquity, the variation in the intensity (both "natural" and through cut-off) of the image from the centre to the margins of the field can be expressed numerically. The exposure required in each marginal zone will then be inversely proportional to these figures, and can be charted in the manner already shown for "natural" reduction of intensity in fig. 8.

From these two lines of reasoning and experiment it is seen that with the most perfect lens the image intensity inevitably falls off to a considerable extent outside an angle of view of about 50°, equivalent to the use of a lens of focal length equal to the diagonal of the plate: also that when cut-off of marginal

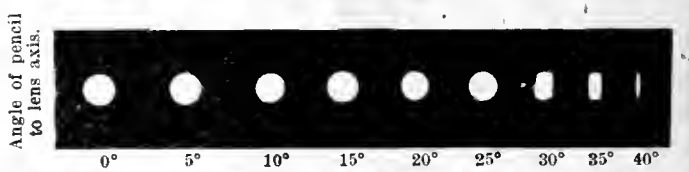

Fig. 12.—Relative effective diaphragm apertures for same anastigmat as Fig. 11, but with $f/15.5$ stop.

rays by the lens is added to this natural reduction of marginal image intensity, the effect sets in nearer to the centre of the field and becomes much greater, particularly in the case of the older types of lenses, such as rapid rectilinears of $f/8$ aperture. Use of a small stop will generally equalise unevenness of illumination due to cut-off by the mount, but has no effect on that due to the three-fold cause, which has been called "natural." The concurrent action of the two effects is responsible for some curious anomalies. For example, Zschokke has shown that of two lenses, an $f/6.3$ aplanat and $f/6.8$ anastigmat, the former is more rapid than the latter within an angle of view of about 20°. Outside this angle—that is to say, towards the edge of the field—the image is better illuminated with the anastigmat than with the aplanat. The case is worth citing, as emphasising that the conventional F. No. rating of lenses is a very partial measure,, and may at times be highly misleading as an indication of the comparative speeds of two lenses of different types.

Absorption and Reflection.

There remain also the effects of absorption of light by the glasses of a lens and reflection from the free surfaces of its components. Both of these factors are commonly neglected in

the rating of lenses for "speed," as regards both the centre and the margins of the field, although it cannot be said that either is negligible. Moreover, the reduction of intensity of image produced by a lens owing to its departure from the ideal colourless, transparent and non-reflecting instrument can be calculated, and if opticians so choose, expressed as a coefficient increasing the F. No. to a greater or less extent: or the speeds of actual lenses could be more accurately indicated in relation to each other as when Zschokke, by taking into account both absorption and reflection, found that a Dagor at *f*/7.5 had the same speed as a Syntor at *f*/6.8.

Few data respecting absorption of light by the glasses of lenses are available, but, apart from the rare instances of yellowing with age and exposure to light and the less rare cases of greyness of the glasses in a newly-manufactured objective, there appears to be a great variation—2% to 12%, among optical glasses as regards absorption of violet light. When it is also considered that absorption increases in geometrical ratio with the thickness of the glass, it will be understood that from this cause the 3-in. lens of a vest-pocket camera may be appreciably faster than one of the same relative aperture but of, say, 9 in. focal length.

The reduction of intensity by reflection of light has been commonly estimated on the basis of a loss of 5% of the light reaching each air surface in the lens. On this basis the loss in the case of two air surfaces (a single lens) is 10%; of four, 19%; of six, 26%; and of eight, 34%. Hurter and Driffield, adopting a somewhat higher coefficient of reflection, considered the differences between single, doublet and triplet lenses to be sufficient to justify provision for them in the design of their actinograph or exposure-meter. Reflection losses, on the other hand, are independent of the size of a lens.

To conclude, in view of the considerable and irregular loss of marginal intensity with wide-angle lenses and of the appreciable differences which are liable to occur by absorption and reflection, the relative aperture or F. No. of a lens must be regarded as a rough measure of "speed," valuable for indicating a range of required exposures of the order of 1 to 2,000, but leaving out of account other factors which may have a substantial effect upon the shortness of exposures permissible with a given instrument. Considering the advances in the speed of lenses which have been made and continue to be made, the question may be asked of opticians whether a more refined system of marking lenses for speed is not now required.

G. E. B.

FOCUSSING INTERIORS BY SCALE.

[In the following article from the "Camera," the author, Mr. William S. Davis, gives a useful series of tables for use as a guide in obtaining the greatest depth of focus by setting the focussing scale of a hand camera to a certain distance (somewhat further than that of the nearest object required in focus) according to the degree of stopping down of the lens.—EDS. "B.J."]

As the more advanced readers know, a lens, when set on the focus-scale for a near object, will not produce a clear image of a distant one at the same time when a large lens-stop or diaphragm is used, but the ability of a lens to render near and distant parts clearly simultaneously, which is called "depth of focus," is much increased when the size of the diaphragm is reduced. The smaller the lens-stop through which the image-forming rays of light have to pass, the greater the depth, which is the reason why one is told to "stop down" a lens when taking a subject containing both near and distant objects which it is desired to have sharp in the picture.

When stopping down to increase the depth of focus, many make the mistake of setting the lens-pointer upon the focus-scale for the same distance as the nearest object is from the camera. This is quite right when such an object is the only one to be considered, and the lens is being used at its largest aperture, but it entails the employment of a needlessly small lens-stop to bring distant parts into good focus. The reason for this is the fact that a smaller lens-stop not only increases the depth of focus *beyond* the point for which a lens is set, but for *nearer* parts as well, so one can take advantage of this to "split the difference" when focussing. In other words, set the lens for a point somewhat beyond the actual distance from the camera of the nearest object one wishes to have clearly defined, and in this way secure good definition upon both near and distant parts with a larger lens-stop than would otherwise be necessary.

To avoid using a needlessly small lens-stop, on many occasions it is well worth while to know the depth of focus possessed by the lens one's camera is fitted with for each stop used. This knowledge is especially valuable when photographing interiors, whether in the home or a large public building, since good definition is called for in all parts of such subjects, yet owing to the lighting frequently being weak, the employment of an unnecessarily small lens-stop would greatly prolong the time of exposure. Most workers, however, not knowing how much depth of focus to count upon at a particular stop opening, simply stop the lens "way down" to make sure of getting the depth desired, which is often unnecessary.

While I might give the formula for figuring the depth of focus, I know the reader would not care to stop to do this before making an exposure, so have, instead, worked out sets of tables for ready reference, and all the reader need do is to cut out the one which applies to his camera, or copy on a card, which can be included with other accessories in the outfit.

To use with any focussing type of camera, select the table for your camera. Arrange the subject as desired, then measure the distance from the lens, or front of camera, to the nearest object in the scene included within the angle of view. Having obtained this distance, look for the measurement in the left-hand column of the table headed "Distance from lens to nearest object." Opposite the line on which this is found, under "Set lens on scale at," is given the proper distance at which the lens focus-pointer must be set on the camera to produce the maximum depth of focus in this particular case. On the same line in the third column the correct size lens-stop to use is indicated, which will ensure good definition from the nearest part to any distance required for interiors up to approximately forty feet in depth.

Example: One is about to take an interior, or other subject, containing objects at varying distances which should all be in focus, with a 5½ × 3½ size camera. By measurement, the distance from lens to nearest object is found to be 6 ft. This distance is named in the third line of the left-hand column, opposite to which 10 ft. is given as the correct point on the focus-scale to set the lens, while in the last column stop *f* 32 will be found the right size to employ to secure the required definition throughout. One, therefore, pulls the lens-front out to the 10-ft. mark on the scale, moves the diaphragm indicator on the shutter to *f*/32, and goes ahead with the exposure, confident of getting good definition in the negative. If *critically* sharp definition is required, as when the negative must stand considerable enlargement, or the depth of the interior is greater than 40 ft., the next smaller lens-stop than one indicated in the table should be used.

If the exact measurement for distance from lens to nearest object is not found in the first column, take that for the next nearer. For example: If the distance happens to be

6½ or 7 ft., take 6 ft. in the table, for it is obvious if an object as near as this is in good focus, the one further removed will also be sharp.

Naturally, a fixed-focus camera is much limited in scope for use upon very near objects, since the lens is set to give the best results for the average outdoor scene, but objects quite near can be made reasonably clear in the picture by "stopping down" the lens. The table for fixed-focus cameras will therefore be useful to users of that type of instrument, as showing the nearest object which will be in focus with each size of lens-stop, including, of course, all that lie beyond.

Regarding the sizes of stops on this table. Some cameras, such as the simpler small boxes, have the lens-stops numbered 1, 2, 3, etc. When such is the case, stop 1 can be considered the same as "*f*/11" on the table; No. 2 as "*f*/16," and so on.

Just to prevent possible confusion in making calculations, it is well to mention the fact that two systems of marking diaphragms are still in common use on the better grade lens—the "*f*" and Uniform System, the latter usually known as "U.S." Practically all the anastigmat lenses have the stops marked by the "*f*" system, while in most cases the outfits fitted with single achromatic and R.R. lenses have the "U.S." numbers on the diaphragm scale. One can tell which is used at a glance, since with the "U.S." system each size smaller stop is marked with twice as high a number as the preceding one, which on a good R.R. lens makes the scale read 4, 8, 16, 32, 64, 128. When the "*f*" marking is used, each smaller stop bears a number only about half as high again as the previous one, making the same-sized stops as those of the "U.S." system read *f*/8, 11, 16, 22, 32, 45. Whichever system is used, each smaller stop opening requires just twice as long an exposure as the next larger one preceding.

When possible, it is better not to include objects very near the lens when taking an interior view. By keeping the nearest parts as far away as circumstances permit, the depth of field is reduced, thus making it possible to use a larger lens-stop than would otherwise be needed, while the chances of having the nearer objects appear exaggerated in size will also be practically eliminated, to the great improvement of the composition.

A direct-vision finder will prove helpful in arranging the composition, as one can more easily note the relative position of details than is the case when depending upon observance of the small image given by the ordinary reflecting finder. A simple cardboard frame, with a sight aperture placed in the position from which can be seen the same angle of view included by the lens, serves the purpose.

SPECIAL FOCUSSING TABLE FOR USE WITH FIXED-FOCUS CAMERAS.

	Stop F/11, or U.S. 8	Stop F/16, or U.S. 16	Stop F/22, or U.S. 32	St pF/32, or U.S. 64
1⅝ × 2½ Camera ..	8 feet	6 feet	5 feet	4 feet
2¼ × 3¼ Camera ..	12 feet	9 feet	8 feet	6 feet
3¼ × 4¼ Camera ..	16 feet	12 feet	10 feet	8 feet

FOCUSSING TABLE FOR 2¼ × 3¼ CAMERAS
(Lens of approximately 4-inch focal length)

Distance from Lens to nearest object	Set Lens on Focus-scale at	Use Lens-stop
4 feet	6 feet	F/22, or U. S. 32
6 feet	10 feet	F/16, or U. S. 16
8 feet	10 feet	F/11, or U. S. 8
10 feet	15 feet	F/8, or U. S. 4

FOCUSSING TABLE FOR 2¼ × 4¼, 3¼ × 4¼, AND 2¾ × 4¾ CAMERAS
(Lenses not over 6-inch focal length)

Distance from Lens to nearest object	Set Lens on Focus-scale at	Use Lens-stop
4 feet	6 feet	F/32, or U. S. 64
6 feet	10 feet	F/22, or U. S. 32
8 feet	10 feet	F/16, or U. S. 16
10 feet	15 feet	F/11, or U. S. 8

FOCUSSING TABLE FOR 4 × 5, and 3¼ × 5½ CAMERAS
(Lenses not over 7-inch focal length)

Distance from Lens to nearest object	Set Lens on Focus-scale at	Use Lens-stop
4 feet	6 feet	F/45, or U. S. 128
6 feet	10 feet	F/32, or U. S. 64
8 feet	10 feet	F/22, or U. S. 32
10 feet	15 feet	F/16, or U. S. 16

The figures under each stop number indicate distance from lens of the nearest object which will be in sufficiently good focus when that sized lens-stop is used. All parts beyond the nearest distance named will always be sharp.

If the size of your camera is not listed in the above table, take the next larger size for a guide. The figures given for a 1⅝ × 2½ camera will serve for 2¼ × 2¼ size; those for 3¼ × 4¼ can be used with a 2½ × 4¼ camera, and 3¼ × 3¼ also.

WILLIAM S. DAVIS.

THE ACTION OF AMMONIUM HYDRATE UPON MERCUROUS CHLORIDE.

A Note from the "Chemical News."

When ammonium hydrate is added to insoluble mercurous chloride, the white solid is converted into "black precipitate" of the formula NH_2Hg_2Cl. The equation representing this reaction is usually given as :—

$$NH_4OH + Hg_2Cl_2 = NH_2Hg_2Cl + H_2O + HCl.$$

This suggests that on mixing the reactants, one of which is neutral and the other is alkaline to indicatora, the resultant products should react acid. Actually, it is found that this is not the case, and it was thought desirable to ascertain whether the hydrochloric acid represented as being formed was immediately neutralised by excess of ammonium hydrate.

This appears to be the correct view, since however little of the alkali is used, only one-half of it is accounted for by the above equation, which only represents an initial reaction. The hydrochloric acid produced is only momentarily free; it is immediately neutralised by a second equivalent of ammonium hydrate.

Quantitative experiments have been carried out to elucidate the nature of the reaction as follows :—

Mercurous chloride (0.942 grm.) was placed in a conical flask of 200 cc. capacity, and shaken with 10 cc. of water. 20 cc. of a normal solution of ammonium hydrate were added, and the whole was shaken, after inserting a stopper, and allowed to stand for 15 hours. The mixture still evolved the odour of ammonia, and was quickly filtered into a graduated flask (200 cc.), and the precipitate was washed several times with water. The volume of filtrate and washings was made up to 200 cc. 20 cc. were withdrawn and titrated against a decinormal solution of hydrochloric acid. This was repeated twice. The 20 cc. of filtrate required :—

Expt.	cc. $\frac{N}{10}$ HCl
1	8.00
2	7.90
3	7.95
Mean	7.95

Thus the free ammonium hydrate in the total filtrate was 0.556 grm. The quantity actually taken was 0.700 grm., therefore 0.144 grm. was used in the course of the reaction. The amount of soluble chloride ions formed was estimated as follows :—

20 cc. of the filtrate made up to 200 cc. were withdrawn and boiled for 15 minutes to drive off all free ammonia. The residual solution was then titrated with a fiftieth normal solution of silver nitrate, using potassium chromate as indicator. This was also repeated twice, and the following results were obtained :—

Expt	cc. $\frac{N}{50}$ $AgNO_3$
1	9.20
2	9.15
3	9.10
Mean	9.15

Thus there was 0.098 grm. of ammonium chloride in the whole solution.

These results are accurately expressed by the equation :—

$$2NH_4OH + Hg_2Cl_2 = NH_2Hg_2Cl + NH_4Cl + H_2O$$

which requires that for 0.942 grm. of mercurous chloride, 0.140 grm. of ammonium hydrate should be used and 0.107 grm. of ammonium chloride should be obtained.

A difference of opinion exists regarding the nature of the black precipitate NH_2Hg_2Cl. Some chemists consider it to be a mixture of white precipitate, NH_2HgCl and metallic mercury. If it is rubbed on to copper it does not amalgamate or perceptibly affect this metal. This is hardly to be expected if free mercury were present. Hence it seems more correct to regard the substance as a compound and not a mixture

J. G. F. Druce, M.Sc., A.I.C.

FORTHCOMING EXHIBITIONS.

September 10 to October 8.—London Salon of Photography. Hon Secretary, London Salon of Photography, 5a, Pall Mall East, London, S.W.1.

September 19 to October 29.—Royal Photographic Society. Secretary, Royal Photographic Society, 36, Russell Square, London, W.C.1.

November 17 to 19.—Bowes Park and District Photographic Society. Particulars from the Hon. Sec., S. Smith, 68, Mannock Road, Wood Green, London, N.22.

December 3 to 17.—Scottish Photographic Circle. Hon. Secretary, W. S. Crocket, 10, Parkgrove Terrace, Tolleross, Glasgow.

1922

January 21 to February 4.—Partick Camera Club. Particulars from the Hon. Secretary, James Whyte, 51a, Peel Street, Partick, Glasgow.

February 14 to 17.—Exeter Camera Club. Particulars from C. Beauchamp Hall, Hon. Exhibition Secretary, Exeter Camera Club, "St. Denys," Bellevue Road, Exmouth

Patent News.

Process patents—applications and specifications—are treated in "Photo-Mechanical Notes."

Applications, September 5 to 10:—

Colour Photography.—No. 24,133. Production of natural colour photographs. S. J. Cohen

Cinematography.—No. 23,999. Cinematograph apparatus. G. Greenway.

Colour Photography.—No. 23,625. Colour photography. R. H. Martin and F. M. Robb.

Stereoscopy.—No. 23,858. Means for obtaining stereoscopic pictures. E. M. Wright

The following complete specifications are open to public inspection before acceptance:—

Process.—No. 168,578. Process for the production of gelatine printing plates. H. Renck.

Applications, September 12 to 17:—

Shutters.—No. 24,201. Photographic shutters. Akt. Ges. für Feinmechanik (R. Haddon).

Photography.—No. 24,506. Photography. H. C. Austwick and R. Kohler.

Film Devices.—No. 24,278. Portable holding-device for handling photographic films. J. H. Rigbey.

Colour Cinematography.—No. 24,351. Production of colour play pictures. H. L. Stoltenberg.

Distance-Recorders.—No. 24,683. Camera distance recorder. H. E. Unwin.

COMPLETE SPECIFICATIONS ACCEPTED.

These specifications are obtainable, price 1s. each, post free, from the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C.

The date in brackets is that of application in this country; or abroad, in the case of patents granted under the International Convention.

Cinematograph Projection Screens.—No. 167,340 (May 26, 1920). The cinematographic picture is projected through a translucent screen in front of which (*i.e.* on the same side as the spectators) and at an angle thereto is arranged a transparent screen having a reflector disposed for reflecting uniform light thereupon.

In the drawings, A indicates the projector placed behind the screen B, the screen being made of translucent material; the

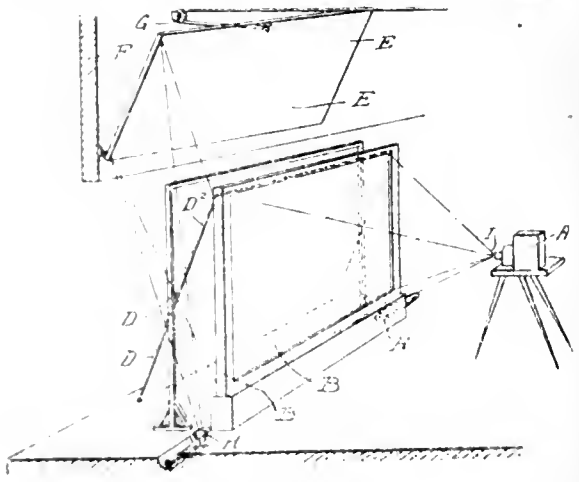

Fig. 1.

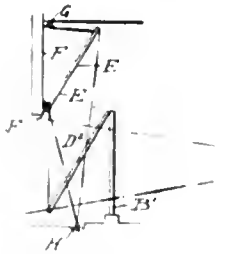
audience is seated in front of the screen in the space indicated by C. D indicates a second screen of transparent material such as clear plate glass supported in swinging relation to screen B. The screen D is supported in a frame D^1 that can be moved relative to the frame B^1 which holds the screen B. E indicates a reflector which is located above the screen D with its reflecting surface arranged parallel with the surface D^2 of the screen D. The reflector E is supported on the wall F by means of hinges, one of which is indicated by F^1, and by means of a cord and pulley combination G, the reflector may be adjusted in proper relative position to the screen D.

The reflecting surface E^1 is preferably a cloth fabric of light brown material having a glossy surface which reflects the light projected thereon from the lamps H and H^1 respectively, placed at each side of the screen B and far enough away from the frame B^1 to permit the light to fall full upon the entire surface



of the reflector E, and the light is reflected on to the surface D^2 of the screen D. The light from the lamp I of the projector A conveying the picture is thrown on to the screen B, and the picture is then visible to the audience.—John Frederick Robert Troeger, 648, East 34th St., Brooklyn, New York State, U.S.A.

Rotary Print Dryers.—No. 165,529 (March 29, 1920). The invention relates to apparatus for drying prints in which the prints are passed between two endless bands round a heated drum, and consists in providing means for controlling the length of contact with the drum and in the structural framework of the apparatus.

The endless aprons pass round rollers *b*, *k*, the latter of which is mounted on pivoted arms *j* and can be adjusted towards or away from the periphery of the drum *a* by screw nuts j^6; alternatively, the roller *k* may be mounted in a bracket slidably adjustable towards and away from the periphery of the drum. Means may be provided to hold the roller *k* in any adjusted position.

The framework of the apparatus comprises two frames formed of inverted T shaped rods *c* jointed by chills *d* and braced by

sets of double tubes *e*, *f*, one of the latter being arched as shown. An extending framework *g* of double tubes supports other idler rollers over which the endless belts pass and form a feeding and

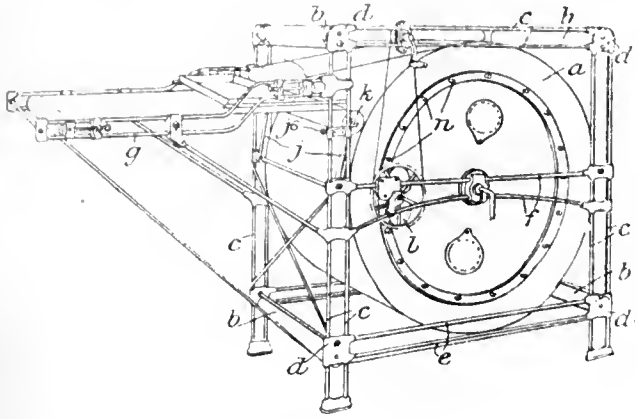


Fig. 1.

delivery platform for the prints. The drum *a* is driven independently of the belts as by means of hand-pulley gearing and a cam *l* shaped to engage periodically pins *n* on the drum, and is

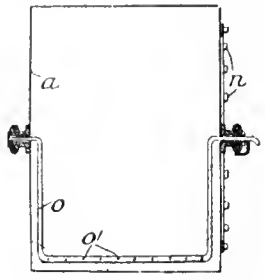

Fig. 5.

heated internally by gas jets *o*, Fig. 5, provided on a stationary cranked gas pipe *g*.—Edwin Charles Bates, 122, High Street, Bordesley, Birmingham, and Charles Howell, 26, Chesterfield Road, Blackpool.

THREE-COLOUR PRINTS.—No. 148,737 (July 25, 1919). The three pictures are formed direct on the celluloid sheet, which is afterwards folded to form the final print. A strip of celluloid has three separate parallel colour fields, and is then sensitised to receive the three separate pictures parallel to one another, whereupon it is developed and washed and the three parts folded one over the other as in the above mentioned arrangement. Thus the pictures are produced on a carrier which forms the permanent carrier for the picture.

A thin transparent, flexible foil which is unaffected by liquids, *e.g.*, celluloid of about .04mm. thickness, is coated with a layer of gelatine in such a way that three adjacent equal sized colour fields, each of the size of the negative employed, result.

To this gelatine film, consisting of three-colour fields, there is added a suitable quantity of sensitive gelatine emulsion, as in the well-known silver bromide pigment process. The back of this foil is laid on the film side of the three negatives so that the yellow colour field lies on the blue negative, the red colour field on the green negative, and the blue colour field on the red negative. The negatives are printed, developed, fixed and washed in the ordinary way. The silver print is then treated in a hardening and bleaching bath, in which the gelatine is hardened according to the strength of the silver deposit, and rendered insoluble in hot water. The silver emulsion may be omitted and pure gelatine and pigment employed, which may then be sensitised with chromates and further treated in the ordinary way. The foil is then placed in warm water and the picture washed as in the pigment process. As the foil is exposed from the rear, any transfer of the picture is unnecessary. The well-washed foil is then dried.

The foil, before being laid on the negative, is twice creased very sharply in such a way that yellow and red meet at the back and red and blue at the film side. The foil is again pulled straight and laid on the negative and further treated. After drying the foil, it is merely necessary to fold the same at the creased places in order to obtain an immediate register, as the negatives already exactly register one with another. For paper prints the folded foil is stuck together with a suitable adhesive and firmly adheres to paper, cards, etc., with the blue film side uppermost. For transparencies the creased foil is mounted between sheets of glass.—Arthur Gleichmar, 82, Albrechtstrasse, Steglitz, Berlin.

New Apparatus.

Quta Letters, Figures and Tablets. Made by the Quta Manufacturing Co., 252-254, Haydons Road, Wimbledon, London, S.W.19.

THESE goods are for the making of attractive notices for show windows and other places, and have the advantage over other outfits, which are now familiar to the passer-by in almost any large street, that the letters need not necessarily be arranged in straight lines, but can be set also in any curved design. The outfit consists of a supply of letters and figures which are made in a composition resembling wood and incorporating some form of adhesive by which they may be immediately secured to a tablet which consists of a stiff board having a celluloid surface. The letters are obtainable in a series of seven colours, namely, blue, red, yellow, black, white, gold and silver, and in six sizes. The tablets are listed in the sizes 9 by 3 inches, 9 by 6 inches, and 12 by 9 inches, at the respective prices of 1s. 6d., 2s., and 3s. 6d. Other sizes at proportional prices. The letters are supplied in assorted lots of 70, at 3s. 6d., of $\frac{1}{2}$-inch size, 4s. 6d. in $\frac{5}{8}$-inch size, and 10s. 6d. for letters of 1 inch. The Quta Company list two standard outfits at the prices of 5s. and 6s. 6d.

The letters are most readily attached to the tablets simply by moistening their backs and pressing firmly into position. For removal it is simply necessary to insert the point of a penknife

after the letter has dried thoroughly on its support. They can, if required, be attached permanently to glass by damping with hot water.

In appearance the notices composed of these letters and tablets are exceedingly neat, and by ringing the changes on the various colours of the letters any required variety may be introduced, quite apart from the facility of arrangement in either straight lines or

curves, which the method affords. We are quite sure that there are many photographers who will find useful applications for the outfits in their show windows, reception and work rooms. It is probable also that use can be made of the letters in "setting up" titles for view negatives, the setting being photographed down on to a process plate for transfer by stripping to the view negative.

New Books.

BIRDLAND STORIES.—This is a nature book for children by Oliver G. Pike, who writes in an entertaining style of the habits of wild ducks, wagtails, gulls and grebes. The book contains twenty-four supplemental plates from photographs by Mr. Pike, and is published by the Religious Tract Society, 4, Bouverie Street, London, E.C.4, price 6s. net.

FIRST AID TO THE AMATEUR PHOTOGRAPHER.—We reviewed this little book by Mr. Will R. Rose of Chester, on a copy of the first edition coming into our hands a few months ago. Although the volume has been thoroughly revised, its plan has not been altered, and, therefore, we cannot say more than we did in writing of the first edition. Nor must we say less, for we think very highly indeed of the book, and repeat that to those multitudes of people whose photography begins and ends with the use of the camera, this is the one manual which they should have. Mr. Rose's book is now published by Messrs. Seeley, Service and Co., 38, Great Russell Street, London, W.C.1, price 3s. net.

New Materials.

ILLINGWORTH PLATES.—An announcement of more than ordinary interest in the photographic trade is that which has just been made by Messrs. Thomas Illingworth & Co., Ltd., Park Royal, Willesden Junction, London, N.W.10, namely, to the effect that they have added the manufacture of dry plates to their long-established business as manufacturers of printing papers. The full list of the Illingworth plates includes fourteen different grades or varieties, inclusive of a rapid and a slow lantern plate. For professional use the four grades which have been designed specially for the requirements of studio and outdoor photographers are the "Studio Fast," "Studio Extra Fast," "Studio Ortho Fast," and "Fleet," the latter a rapid plate for press photography and other high-speed outdoor work yielding clean and contrasty negatives. Plates of special interest to amateur workers are two of lesser speed, namely, a "Special Rapid" and a "Non-Screen." We hope to be able to write at greater length on these new introductions, after having had an opportunity of making trial of samples of the plates which reach us at the time of writing this preliminary note.

PHOTOGRAPHING BATHERS.—The following incident is reported from Broadstairs. A party of girls were enjoying themselves in the water when a young man with the inevitable camera came along. A big wave struck the bathers and spun one of them round until breathless but laughing she was flung on the sand. The force of the wave had pushed the strap of her costume off her shoulder, and just as she noticed it and hurriedly replaced the strap she heard the click of the camera and saw the man's grin. The girl jumped up from the water and advanced to the man, who was trying to replace his camera in the bag hanging on his arm. Not a word was spoken, but the girl snatched the camera out of the man's hand, and, evading the astonished photographer's grab, flung the camera into the waves. The man looked foolish, particularly as a crowd began to collect. Then the girl recovered the camera, opened it, removed a roll of film, dripping with water, and threw the camera at the man's feet. The young man then slunk away without a word of protest.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

MONDAY, OCTOBER 3.

Bradford Phot. Soc. Social and Musical Evening.
South London P.S. "Architectural Photography." E. R. Bull.
Wallasey Amateur P.S. "Intensification and Reduction" J. Pilkington.

TUESDAY, OCTOBER 4.

Manchester Amateur P.S. Lantern Lecturette. D. M. Paul.
Morley Photographic Society. Whist Drive.

WEDNESDAY, OCTOBER 5.

Partick Camera Club. President's Address.
South Suburban Phot. Soc. "Palestine as I saw it." P. R. Salmon, F.R.P.S.

THURSDAY, OCTOBER 6.

Wimbledon and Dist. Camera Club. "Stories and Glories of Canterbury Cathedral." E. W. Harvey-Piper.

CROYDON CAMERA CLUB

At the last informal meeting, Mr. G. H. Gardner gave a highly interesting lecture-demonstration on "How to Make Money," without reference to prevailing doles. He first said that, owing to the well-known characteristics of some of his fellow-members, he felt bound to point out that the method to be described had inherent disadvantages, usually setting in as a sequel to the work accomplished, which in itself was fairly simple and straightforward.

He then proceeded to give a thoroughly practical exposition of the making of counterfeit coins of nominal value, from sixpence to a sovereign. Apparatus of all description, elaborate and otherwise, was on the table, and the method of working clearly explained. Mr. Sehors, with, apparently, special knowledge, found fault with some of the castings, but the students generally had nothing but commendation to offer.

Almost invariably, the lecturer said, the man who makes the coins does not "utter" them, but passes them on to a confederate, generally a woman—always concerned in any case of mischief. She, in turn, transfers them to the passer of the counterfeit, who takes care only to handle one at a time, so that if nabbed, no other is found on his person. A woman, he added, makes an unreliable crook, as if her delicate feelings are in any way ruffled, she is liable to split.

In the discussion, Mr. Salt inquired how the lecturer had acquired his remarkable skill. "Purely due to a practical application of Einstein's theory of 'Relativity,' and concentration of will," came the reply. Mr. Isaac, who appeared discouraged, thought the game insufficiently remunerative. This view was not shared by Mr. Hibbert, who enthusiastically suggested the starting of evening classes on the subject. Mr. Harpur, speaking in tones of burning indignation, announced that the Bank of England recently had been returning coins which showed any signs of being clipped. He had been much interested in what he had heard. Proposed by the president, Mr. John Keane, a most hearty vote of thanks was accorded Mr. Gardner for an evening of great criminal attractiveness.

Perhaps it would be just as well to add that the lecturer frequently referred to himself in the first person plural. Can it be that the word "we," so often used, indicates connection with Scotland Yard? Many friends of the club will appreciate the gravity of the position.

Commercial & Legal Intelligence.

LEGAL NOTICES.—Notice is given of the dissolution, by mutual consent, of the partnership between Frank Worrell and Henry Pickard, carrying on business as wholesale and retail opticians, at 32, Furnival Street, Holborn, E.C., under the style of The Lorel Optical Company. All debts due to and owing by the late firm will be received and paid by Frank Worrell, who will continue to carry on the business.

A first and final dividend of 3s. 4½d. in the £ has been made in the case of Harold George Webster, photographer, 10, Orchard Gardens, Teignmouth, Devonshire. The dividend is obtainable at the Official Receiver's Offices, 9, Bedford Circus, Exeter.

News and Notes.

PHOTOGRAPHING CATS.—If you want to make a cat comfortable when posing before the camera (writes a correspondent) simply warm the cushion or other article on which the cat is to sit, when pussy will at once become a docile subject. A cat loves warmth and will sit longer and more quietly upon a warm spot than a cold one.

WINTER PHOTOGRAPHY.—Messrs. W. Butcher and Sons send us the 96-page list for distribution by dealers, which calls attention to the many attractive branches of work which can occupy amateur photographers during the winter months. The list deals with enlarging, lantern work, home cinematography, etc., and contains articles on these subjects. Individual amateur workers should apply to their dealers for copies, or send a postcard to Messrs. Butcher, Camera House, Farringdon Avenue, London, E.C.1.

COOKE LENSES ON THE QUEST.—We see from an article in the "Leicester Daily Mail" that Sir Ernest Shackleton selected Cooke lenses for the whole of the photographic equipment which he is taking on the Antarctic expedition. Messrs. Taylor, Taylor & Hobson have supplied him with lenses for cinematography and ordinary camera work, including telephotography. Mr. J. Ronald Taylor, who visited The Quest, reports that he was greatly impressed with the thoroughness of the preparations for the voyage.

THE ENSIGN MESSENGER, Messrs. Houghtons' publication for photographic dealers, contains particulars in its September issue of the Ensign competition for enlargements in which £100 will be awarded in cash prizes. Entries must be received not later than December 31 next. The "Messenger" should be studied by dealers for its particulars and illustrations of the latest introductions of Messrs. Houghtons, which include some neat amateur printing boxes, mounts and albums, box enlargers, and enlarging lanterns.

GASLIGHT PRINTING.—A very practical booklet on the development and toning of gaslight prints has been written by Mr. R. R. Rawkins, of the Rajar Company, and is obtainable free on application to the latter at Mobberley, Cheshire. Mr. Rawkins writes simply and clearly on his subject, and while his aim has been the production of good prints on Rajar gaslight papers, his notes can hardly fail to be of advantage to those employing any gaslight printing material.

"THE CLUB PHOTOGRAPHER" draws the material for the text of its October number from members of the Bury Y.M.C.A. Photographic Society. The chief contributions are a lengthy article on the Paget process of colour photography by A. Benson Ray and another, on pinhole photography, by J. Nichols. Other notes are on the carbon process by Arthur Evans. The fixtures for numerous societies during next month are responsible for the growing bulk of our Liverpool contemporary. Some typographic compression seems to be called for in these pages.

THE SCIENTIFIC AMERICAN announces that from November next its weekly issue, which has appeared regularly for 76 years, will be combined with the "Scientific American Supplement" into a monthly magazine, which will be issued as the "Scientific American." The same large size of page will be continued, and it is stated that the change has been made for the purpose of the better presentation of the scientific and technical matter which has always been a feature of our contemporary. The yearly subscription (United States) of the new monthly will be 4 dollars.

MR. MACKLEM is holding a little exhibition of pictorial photography in his studio at 16, Brook Street, New Bond Street, London, W.1, until October 15. Most of the prints are examples of his own very strong and artistic portraiture, notable among them being portraits of Lord and Lady Byng taken shortly before the former's departure to Canada. Mr. Macklem is a professional worker in the oil process, and a few exhibits on the walls show his excellent technique in this medium. Some Autochrome transparencies are included in the exhibition, and also a number of prints by Mr. John Gear and Mr. Bertram C. Wickison.

LANCASHIRE SOCIETY OF MASTER PHOTOGRAPHERS. — Arrangements have been made to hold the annual meeting of the Society at the Palatine Hotel, Blackpool, on Wednesday next, October 5, at 3.30 p.m. The committee will meet at 2.30 p.m. At this meeting the president and officers will retire, and successors will be appointed. No arrangements have been made this year to hold the annual dinner, in consequence of the great distress. Should there be a sufficient number of members who desire to have an impromptu meal after the meeting, arrangements have been made with the management of the hotel for this to be done.

END OF SUMMER TIME.—The Home Secretary gives notice that summer-time will cease and normal time will be restored at 3 (summer time) in the morning of Monday next, October 3, when the clock will be put back to 2 a.m. The hour 2-3 a.m. summer-time will thus be followed by the hour 2-3 a.m. Greenwich time. All railway clocks and clocks in post-offices and Government establishments will be put back one hour, and the Government requests the public to put back the time of all clocks and watches by one hour during the night of Sunday-Monday, October 2-3. Employers are specially recommended to warn all their workers in advance of the change of time.

A PHOTOGRAPHIC GARDEN PARTY.—The members of the South Suburban Photographic Society were, on Saturday last, invited by Mr. and Mrs. G. H. Dannatt and Mr. P. B. Dannatt to a garden party at their Blackheath home, to meet the new president (Mr. P. R. Salmon), and to inaugurate the autumn session. There was a large attendance, plenty of enthusiasm, surreptitious exposing of plates and films, and "shop talk," the event being the first of its kind in the history of the Society. There were, of course, the usual felicitous and congratulatory speeches, and the party broke up at a rather late hour, well pleased with the excellent start made, thanks to the hospitality of the hosts and hostess.

A BEAR THAT USES PLATES!—A Central News New York correspondent states that a black bear in the wilds of Alleghany has taken a photograph. It is reported that a Mr. R. S. Craig, a forester from the New York College of Forestry, left his camera on a log whilst he looked for a good subject for a picture. He then saw a black bear browsing amongst some berry bushes. In his surprise he did not think of his camera as he sped down the trail to the camp. With two others he went back to the spot, but the bear had disappeared. The camera was still on the log where Craig had placed it, but a plate had been exposed. When the plate was developed it showed Craig in rapid flight down the trail.

FREE-LANCE JOURNALISM.—The business of press photography is now so largely dependent upon a possession of the journalistic instinct, that any course of instruction which contributes to a firmer footing on the journalistic road is of distinct advantage to the tyro in free-lance press photography. It often happens that it is difficult to place photographs simply on their own merits, whereas as accompaniments of a short article they will frequently find a ready market. On these accounts it is worth while to draw the attention of those seeking to earn money by press photography to the course of instruction in free-lance journalism offered by the Practical Correspondence College, 57, Berners Street, London, W.1. We have been interested in reading the very practical advice contained in this course of postal lessons.

PHOTOGRAPHING THE INDIAN ROPE TRICK.—Another attempt to photograph the Indian "rope trick" is described very fully in a new book ("Here, There, and Everywhere") published last Friday. The photographer was Colonel Barnard, at one time chief of the Calcutta police. All the illusionist's operations of throwing up the rope, sending a boy up it, etc., were photographed on "a new roll of film," but, on developing the negatives, none of these operations were pictured on the negatives. The negatives showed the courtyard in which the trick was performed, also the people, including the rope, juggler, and boy, "who had not moved at all." The author, in summing up the mystery, suggests hypnotism and the forcing "the people to see what he (the juggler) wished them to see." The results were the same as those obtained by other travellers who have had the opportunity of photographing the performance of the trick.

A BUSINESS NAMES ACT PROSECUTION.—A case of particular interest to "father and son" businesses was before the courts last week. As is fairly well known, the Registration of Business Names Act makes it compulsory that every firm carrying on business under any name not consisting of the true surnames of all the partners shall be registered. A Mr. G. Arthur Wingfield carried on his business under the name of Wingfield and Son. The Board of Trade discovered that the name of Mr. Wingfield's partner was not "Son," as stated, but was actually "Wingfield." Had they called themselves "Wingfield and Wingfield" or "Wingfields," instead of the more exact "Wingfield and Son," they would not have needed to register—but the words "and Son" laid them open to the attack of people in Whitehall. The firm was not registered, and a prosecution at Bow Street followed, when Sir Chartres Biron described the offence as a

technical one and dismissed the case. The case, says the "Evening News," must have cost each side about £60. The Government Department dealing with the Business Names Act cost £6,260 10s. 5d. in the twelve months ended in June, and its receipts were £4,358 9s. 6d. It has a staff of a registrar and assistant registrar and 40 clerks.

Correspondence.

*** *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

*** *We do not undertake responsibility for the opinions expressed by our correspondents.*

THE SPEED OF SMALL LENSES.

To the Editors.

Gentlemen,—With reference to your interesting article, "The Speed of the Lens," may I ask if there is any explanation of the difference in speed between short and long-focus lenses?

The old box-form pocket Kodak (1½ in. × 2 in. picture, single lens about *f*/13) and the original Verascope (R.R. lenses, somewhat similar aperture) gave fair results in rainy weather with the film and plates of those days. Their shutter efficiency cannot account fully for this.

With my stereo camera (2½ in. focus), one-third the exposure needed with a 6-in. lens suffices. The shutters are nearly akin as regards efficiency.

Glass cuts out the ultra-violet rays to some extent, but I use orthochromatic material, so the thicker glass of the large lens cannot have much influence. Is some form of "scatter" involved?

Though not pertinent to the subject, I may mention that my 2½-in. lenses have a focussing movement which is constantly in use, the effect of the focussing being quite plain in enlargements.—Yours faithfully,

LOUIS NELL.

London, September 22

"A DIRTY LITTLE ROGUE" AT THE SALON.

To the Editors.

Gentlemen,—In criticising my picture as above (No. 82) London Salon of Photography, in your issue of this date, Mr. Tilney appears to have made a remarkable "discovery." The textuous material upon which the baby is peacefully reclining is a concrete floor and the apron of the "pram" is an intervening wall out of focus—hence the vignetted setting. The kiddie had just rubbed his face with road dust. The idea of foamy water just below the edge of a quay is most amusing, and I almost regret having to write this "disillusionment."—Yours faithfully,

JAS. BEARDSWORTH

29, Warrels Grove, Bramley, Leeds.
September 23.

R38 DISASTER PHOTOGRAPHS

To the Editors.

Gentlemen,—As you have published letters from two others in reply to Mr. T. C. Turner's article, in which he claims to have taken the first photographs from the Humber of the wrecked airship, may I, too, be allowed to state my own case, as one of those who signed the letter contradicting Mr. Turner's statement? I am still of the opinion that he is quite mistaken, and that my photographs were actually taken before his. In the first place, I was much nearer to the pier at the time of the disaster, and immediately cycled to the pier, and, seeing a couple of rowing boats leaving for the scene of the disaster, engaged one of them to take me out to the wreckage. I was certainly out on the water some time before Mr Turner arrived at the pier. That can be fully proved, as witnesses who saw the whole proceedings are prepared to testify. Mr. Turner also states that the tug which took him out had already made a trip out and brought in a survivor. It would take quite five minutes to reach the wreck, and not less than ten minutes to search the wreckage and rescue Captain Wann, who, I believe, was unconscious at the time, five minutes to return, and at least another five to get stretchers and move the captain on to the landing-stage. Then the second trip out must have taken at least ten minutes to take soundings and get into position for Mr. Turner's historical picture. That means over half-an-hour must have passed before Mr. Turner took his photographs. This is fully borne out by his statement that there was no part of the forepart of the airship visible when he went out except a few blazing and smoking pieces. When I went out we passed a considerable amount of wreckage out of the water, quite apart from the burning portions, which were chiefly petrol. This wreckage was still visible some time after we reached the after-part of the airship, but had disappeared on the return journey.

On one of Mr. Turner's photographs two boatloads of men are to be seen, one of them most likely the boat I engaged, and the other the one that set off at the same time. If it were not so, as Mr. Turner claims, the fact that boatloads of men had reached the scene is surely enough proof that it was possible for other boats to have done so. I am quite certain there were no fully-loaded boats on the scene when ours arrived, as we rowed all round the wreck to look for survivors. There were one or two boats on the scene which contained only one or two men. I make no pretence to have taken the first photographs, but do claim to have beaten Mr. Turner.

I was quite prepared to let him take all the glory had he not taken so much pains to depreciate the work of other photographers in a journal which appeals to the professional photographer throughout Great Britain and other parts of the world. As a final proof, I enclose a set of prints which I am quite willing to submit to your judgment. I am sorry the selection is not larger owing to an unfortunate accident on the rowing boat, when my camera bag was overturned and nearly a dozen plates were dropped into the river. Still, those sent are quite sufficient to show that no breaking up of the after-part had taken place when they were taken. The one showing the wrecked girders was taken from the end that had broken apart, and is probably the only view taken looking right into the opposite end, from which most of the photographs were taken, as probably it was quite unsafe for anything else but a rowing boat to approach.

A great part of the damage done later was caused by two powerful tugs, which attempted to pull the wreckage over in case there were any of the ill-fated crew underneath. Instead, it was pulled to pieces, at the same time sinking into the sand and being covered with the rising tide.

Mr. Turner's letter published in your last issue I will leave, except that part which deals more directly with myself, being one of those pressmen who frequently turn up, nearly always "on invitation" when Mr. Turner is on the scene. If not invited, I am always sent as a representative of the "Hull Daily Mail," I never interfere with him in any way if I can possibly help it. But to be told at a "public event" that he cannot allow anyone else to take photographs, and that the Press must take their pictures from him, is taking up a position which in these days (when the recognised Press photographers have every assistance given them by those in authority) is a very undignified one.

As an illustration of Mr. Turner's judgment of a Press picture, the fire and smoke picture, which he did not think worth a plate, and was taken, he says, with a small camera from the pier, the leading newspaper in which Mr. Turner's "star" picture appeared paid £100 and £20 cab fare to London for it.

As for editors using professional studio workers' photographs in preference to pressmen's work—well, editors are human, and naturally use that which costs them nothing.

With apologies for taking up so much space with the first letter I have ever written to the Press.—Yours sincerely,

G. H. HARNESS.

7, Elsie Villas, Holland Street, Hull.
September 26.

[Mr. Harness sends us four of his photographs of the wreck (unmarked as regards order of taking), and the last one of Mr. Turner's for comparison. Three of these views, all of which were taken at comparatively close range, do not show the wreck from stem to stern as do the earliest of Mr. Turner's. The fourth does show the wreck under this aspect, but in our judgment at a later stage of

collapse than the earliest of Mr. Turner's. In view of what has been said of the rapidity with which the structure changed its shape under the action of the tide, we imagine there was a comparatively short interval of time between the exposures by the respective photographers.—Eds. "B.J."]

To the Editors.

Gentlemen,—Mr. T. C. Turner places the responsibility for our letter on Mr. Watson. I signed it, and, apart from the mistake which I corrected and apologised for, I agree with the contents.

Photographs taken by Mr. Harness have now been forwarded to you. When comparing the various photographs, I would ask you to remember that the tide was rising and the wreck gradually collapsing.

In the light of facts with which he is now acquainted, does Mr. Turner still claim to have taken his photographs about an hour before those of any other photographer? Stripped of all its trimmings, that is the inference his article conveys.

As regards my own photographs, you commented as follows:—"It is possible to say, with reasonable correctness, that the last of Mr. Turner's photographs to be taken shows the wreck in approximately the same state as does the first of Mr. Overton's." How then, does Mr. Turner justify his assertion, "And they" (the other men with cameras), "arrived on the scene when the wreck had broken up a great deal by the action of the tide"?

I have kept strictly to the points that have been raised. I would ask Mr. Turner to do the same.—Yours, etc., F. OVERTON.

85, Prospect Street, Hull.

September 26.

"PLATES *VERSUS* FILMS."

To the Editors.

Gentlemen,—The correspondence on films and plates is disappointing in one respect. With the exception of my own letter no reference is made to the new Board of Trade draft regulations as to storage of celluloid. This is of serious consequence to all those who have been using films since their introduction, because they must have accumulated a hundredweight or more of celluloid, which may mean, under new regulations, the construction of a fire-proof chamber in which all the stock celluloid and nothing else must be stored. This will be a very serious matter for some of us, especially those who are cramped for space and money. In my own case I do not see how it is possible to find room for such a place, and many others must be in a similar position. It is quite impossible to get more accommodation in this town, the demand for offices greatly exceeds the supply, and for quite a small room in a side street a rent of £50 a year is asked; to this must be added rates of 18s. in the pound, nearly doubling the rent, and gas at 5s. 6d. per thousand cubic feet, and so on.

This seems to me the point which decides whether we shall use plates or films. On the question of quality and convenience every photographer can decide for himself, but in the matter of storage he has no option but to obey whatever law is enforced or take the unpleasant consequences of defying it. I don't think for a moment that any objections on our part will stop the new regulations coming into force, because, after all, we are not obliged to use films, we can go back to glass, though many may be reluctant to do so. I hope we shall hear from other photographers what their ideas on the subject are on this matter of storage. Acrimonious remarks on the virtues and vices of plates or films do not get us any "forrarder."—Yours truly,

HAROLD BAKER.

To the Editors.

Gentlemen,—With your permission I would like to add the following remarks to my already-published letter, and then I hope just to look on while the discussion continues.

My critics seemingly forget that Messrs. Kodak's "Announcement" was based upon three main clauses: (1) Their decision not to manufacture any more glass plates, (2) an assertion of the superiority of film over plates, and (3) a statement which implied that only back-numbers in the photographic fraternity were users of plates to-day.

The first statement should concern the firm alone, the second is debatable, while the third is a remark which, to my mind, is unwarrantably assertive and should never have been made. It was to the covert attack implied in (3) that Mr. Lambert drew attention, and to which I appended my supporting protest. The distinction was appreciated by you, gentlemen, as is shown by the two headings used. The original heading, "The Kodak Manufacturing Policy," has now become "Plates *versus* Films." Messrs. Kodak entangled them together, but film enthusiasts bid me concentrate on the latter subject only. I have no doubt whatever that this is what Messrs. Kodak would prefer, but I cannot believe that those members of my profession who use portrait film would assent to the implied slur on those who do not. "Chacun à son gout." Those who differ from me on this aspect of the matter may say so.

To continue. When "portrait" film was brought to my notice, I tried it as I would try anything which might help me to improve my business. I could not do more. It did not suit me, and so I dropped its use. I did not bother any further about it until I was up against the suggestion that, speaking generally, I was "an unprogressive person, opposed to change of any sort." I object to *that* label. Anyone who can show me what might be to my advantage is ever welcome, but I claim the right of rejection without the makers' further comment if the goods are found wanting. A little less of the "high falutin'" on Messrs. Kodak's part and all would have been well, so far as I am concerned. The discussion in such a case would have been confined to the simple question, "Which is the better for the professional user—plates or film?

With respect to this latter question, it might be of interest if I state how I came finally to eliminate the use of film from my working. I first tabulated what I considered to be the essential requirements in my *ideal* negative-making medium. These were as follows:—

(*a*) Rapidity; (*b*) freedom from chemical fog, combined with latitude in development in case of necessarily brief exposure; (*c*) density-giving power; (*d*) non-halative property; (*e*) amenity to any needed after-treatment, *i.e.*, intensification or reduction; (*i*) indestructibility, *i.e.*, non-breakage, non-inflammability; (*g*) speed in working when urgency demanded; (*h*) absolute flatness and rigidity when in use; (*i*) correct monochromatic rendering of colour-values; (*j*) keeping qualities—especially prior to development; (*k*) cost to buy.

I do not pretend that these items are placed in strict order of importance, for this would naturally vary according to the requirements of each individual worker. I do, however, consider it essential that such a list should contain only those properties which the negative-making medium would inherently possess. I mean by this that such points as, for instance, difficulty in retouching, should be looked upon as being purely personal factors, dependent to a very great extent on the idiosyncrasy of the worker.

I think that if discussion centred on the fixation of such points as these, each worker could then quickly decide for himself as to what would best meet his requirements. (Lady readers, please consider yourselves included, where necessary. I am no misogynist). Now, to me, with the preceding list before me, the advantage of plates over film was manifest in items (*a*), (*b*), (*e*), (*g*), and (*j*), while films scored with items (*d*) and (*k*). I considered that (*c*), (*f*), and (*i*) were really neutral, with a slight advantage for plates in (*i*), assuming a good non-filter type of plate to be used. While again, as regards (*d*) and (*k*), a well-backed plate has hitherto done all that I have asked of it, and done it well. As for cost, I have never considered this if I could get definite practical advantages by paying a bit more.

Undoubtedly, the principal factor is the question of support for the sensitive emulsion. Glass is breakable and thick, hence its halative tendency. Celluloid is highly inflammable and easily scratched, while it has, more or less, to take its own time in drying. Can anything else be substituted which would be minus these defects, inexpensive to manufacture and highly transparent? Should something eventually be evolved, I promise that I shall not be found "resistant to progress."

A few words now to certain of my critics. Mr. W. E. Debenham inquiries what justification exists for my implication that films

are slower than plates. They were most definitely so with me, but no doubt he has since read what Mr. Harold Baker says on this point on the very same page as Mr. Debenham's own letter. But why do Messrs. Kodak not indicate the speed of the film on the package?

As regards Mr. Will Cadby, his suggestions (well meant, I am sure) seem to be quite impracticable. What period would he assert to be the minimum for fair and adequate trial of a new production? And what quantity must be used in any such trial? Would he try everything that is offered? (To keep exclusively Messrs. Kodak's productions would scarcely be fair to other manufacturers.) Will he assert, in addition, that the full extent of the trial must be made both by technical expert and by novice, that both will then be equally competent to pronounce a verdict, and that in such case agreement will be unanimous? And so on. Respecting his second condition, I concur on the understanding that it applies *all round*—in this case, to Messrs. Kodak as well. And then, where are we? No, no, Mr. Cadby. Think it out a little bit more, and, *please*, do not think me personal in asking this, any more than you meant to be with me. And I really do not consider Mr. Cadby's reference to the Swiss mountains at all germane to the present discussion; at least, none such have ever yet put in an appearance in my studio, while *portrait* film for photographing *mountains* seems somewhat anomalous.

I am rather disappointed with the majority of the letters so far published. Mr. Harold Baker's, I think, was a real contribution to the discussion. Your correspondent, "Fair Play," preaches a sweet reasonableness, in which I am all with him. But why the nom-de-plume? The letter reads rather like one from a trade finisher, but I can see nothing in it to demand the anonymity, which spoils it. He is the only instance of this, too.

Just one little thing in conclusion. Let us consider the case of the Press photographer, whose very calling compels him to take no chances with his work. Those with whom I have discussed the point have expressed a preference for plates. For what reason? Because they are far more dependable than any film yet produced. And so, still, say I. Yours faithfully,

Shrewsbury. J. MALLINSON.
September 23.

To the Editors.

Gentlemen,—There has been so much discussion as to the relative qualifications of plates and film that I feel it is only fair (having used the film since its introduction), to add my testimony and appreciation of the qualities which the portrait film supplies. It is not always easy to find material that is a real assistance in developing artistic qualities in the work, and I consider that the scale of gradation obtainable with the portrait film, together with the fine grain and the many advantages in manipulation combine to make the portrait film a real assistance in the artistic workers' hands.

Would to heaven we could persuade our paper manufacturers to produce a paper that would yield a greater degree of atmosphere, which quality only the Platinotype print can boast; but whilst we remain content with the old and pay well for it, there are few manufacturers who will stir themselves to greater effort. All honour then to the Kodak Co. for succeeding in giving us some thing better in material to enable us to produce better work.—Yours faithfully, EDWIN LUKER, F.R.P.S.

30, Old Christchurch Road, Bournemouth.
September 20, 1921

To the Editors.

Gentlemen,—Throughout the controversy now raging re the respective claims of plates v. films, one point seems to be continually cropping up, viz., speed.

It is generally admitted that the films now on the market are not so fast as the very fine plates obtainable from various makers, and to the worker who depends entirely upon electric light, this is a big point.

Some of your correspondents hopefully suggest that no doubt films could be made as fast as plates.

This subject always reminds me of an occasion some years ago, I think it was before the portrait film was much heard of. Members of the P.P.A. congress were visiting Barker's studios at Ealing, and in an informal talk which followed Mr. Barker, with great geniality and, I believe, considerable authority, explained many interesting things to us.

The query was raised as to why films should be slower than glass plates, and it was then stated that if an emulsion of a certain speed was taken and one-half of it coated upon glass, and the other half upon film—when used, the portion upon film would be found to be considerably slower than the portion upon glass.

If this is correct, then there would seem to be some inherent quality in the film which is antagonistic to the most delicately sensitive state of photographic emulsion.

If there is little in it, or if it can be overcome, Messrs. Kodak, Ltd., may yet pamper us with a combination of their ideal, but highly delicate emulsion, Wratten Panchromatic, served upon their "ideal" base.—Yours faithfully, A. W. H. WESTON.

8, Bank Parade, West Kensington, W.14.

Answers to Correspondents.

In accordance with our present practice a relatively small space is allotted in each issue to replies to correspondents.

We will answer by post if stamped and addressed envelope is enclosed for reply, 5-cent International Coupon, from readers abroad

Queries to be answered in the Friday's "Journal" must reach us not later than Tuesday (posted Monday), and should be addressed to the Editors.

K. N.—The maker of the jig-saw photographs is Mr. Campbell Gray, 88, Edgware Road, W.2.

G. R.—The Packard Ideal shutter can be used very effectively in a double camera front—that is to say, the shutter sandwiched between the original front and an extra lens board. The instantaneous exposure is quite fast enough for moving objects at ordinary speeds.

W. R.—One ounce of bicarbonate of soda in about 50 or 60 ozs. of water would be a suitable formula. The bicarbonate is used up by being neutralized by any acids in the emulsion coating, and, therefore, it is well to use plenty of the bath, so as not to exhaust it. Immersion of the prints for five minutes is ample.

S. H. C.—If you took the group "on your own"—that is to say, did not receive an order from the club, and therefore are not looking to the club for payment, then copyright in the photograph is yours, and any reproduction of the photograph is an infringement in respect of which you can demand a reproduction fee, or, if the people won't pay, can sue them in the County Court.

H. A.—We advise you to get the "Writers' Year Book," published by Messrs. Black, and obtainable through any bookseller. It gives particulars of the chief periodicals in this country and America, with brief notes on their preferences both as regards illustrations and literary matter. Another book, which it would be worth your while to get, is "Willing's Press Guide," price 2s., from Messrs. Willing, King Street, Covent Garden, London, W.C.2. It is a complete classified directory of the Press in this country, and contains also particulars of leading journals abroad.

W. A.—(1) The feasibility depends on the size and illumination of the room. Whatever lens you use, whether small or long focus, the sitter should not be closer to it than 10 ft. or 12 ft., and, therefore, this very greatly limits the size of the room which can be used for portraiture. (3) The cross front is a sliding movement of the lens horizontally. (4) They are quite convenient in use, but one drawback which occurs is that the film does not lie as flat as a plate, and for this reason no doubt, and also on account of the lesser facility in handling in enlarging and printing, plates are preferred. (5) Quite impossible to say with any degree of approximation. From the definition and the drawing we should say that the group was taken with a lens of at least 8 ins. or 9 ins. focal length. It might, of course, have been longer.

RETOUCHING.—I have been making an enlarged portrait negative on a 12 x 10 plate, and experienced some difficulty in potting retouching medium on so large a surface. (1) Would you kindly tell me what is the best way to apply the medium on large plates? (2) If spotting has to be done to block out pinholes, I presume it must be done after the medium is on, but it does not appear to adhere on the medium's surface as well as it does on the plain gelatine surface.—A. T.

(1) The best way to apply retouching medium to a large surface is to wet a corner of an old silk handkerchief or piece of china silk with the medium, and to rub gently and quickly upon the film. (2) The pinholes may be stopped out before putting on the medium if a little gum is mixed with the colour; this will prevent it from shifting when the medium is rubbed on. It is quite easy to put colour on the medium when the latter is perfectly dry.

A. B.—We should think you can bring the negatives to uniform printing density for simultaneous printing simply by using a greater or less number of sheets of thin tissue paper under each, as is done by the rotary printers of postcards, who thus "even up" a score or so of copy negatives. Certainly, in making such copy negatives it is possible to get a pretty even match throughout; nevertheless, the system is one which can be used for negatives which are of considerable difference in density. The worst of it is, of course, that it slows all down to the printing speed of the densest. If you have to reduce, we advise a very weak Farmer's reducer of pale lemon yellow colour. For intensification probably the best plan would be to use the chromium intensifier in the form which gives the least increase of density (page 439 of the current "Almanac"), repeating the process as required and ascertained by testing the evenness of the negatives together by making a print

T. O.—At the present time there is no paper on the market which, by the ordinary processes, yields a positive image in the camera, or photo-micrographic camera. The only thing of the kind is the so-called ferrotype card or plate, which is a sensitive material of black colour having an emulsion coated on it. Development is done with a solution which gives a whitish image, so that what is really a negative appears as a positive, the shadows being formed by the black substratum and the so-called "whites" by the developed image. But we do not think that the somewhat degraded gradation of the results produced in this way would be satisfactory for your purpose. No doubt you know the kind of thing which is made by the beach photographer. There was formerly a paper on the market which gave excellent results for your purpose, the developed image being rapidly reversed from a negative to a positive, as is done in the Autochrome process. This was called "Wernertype," and came from America.

K. H.—(2) The formula in the "Almanac" is the one we recommend for mercuric iodide intensifier, but this is rather a tricky intensifier to make up, and we always advise using the Tabloids of Burroughs Wellcome, or the powder sold by Mr. T. K. Grant, agent for MM. Lumière. (3) The formula for the Kodak amidol developer is:—

Sodium sulphite, cryst.	1 oz.
Water	20 ozs.
Amidol	60 grs.
10 per cent. potass bromide solution	20 drops.

(4) We think the formula you refer to is one recommended in 1911 by MM. Lumière. We have not had occasion to try any of these, and we think that the need of them has been largely removed by the introduction of the Ilford Tropical hardener, supplied by Messrs. Johnson's, which we recommend to your notice for development at high temperatures. (5) The medicated soap is manufactured by Messrs. E. Cook and Sons, The Soapery, Bow, London, E., who would no doubt inform you where you could obtain it locally. Any chemist should be able to obtain it to order.

T. P.—For copying same size, whatever focal length of lens is used, the negative postcard will be two focal lengths from the lens diaphragm, and the sensitive paper will also be two focal lengths from the diaphragm. This is an approximate rule, because with some lenses the distance really requires to be measured not from the diaphragm, but from some point in the lens near to it. To cover a postcard the focal length of the lens should be at least 6 inches, and as the lens is used at twice its focal length the F. No. becomes twice that marked on the mount; that is to say, the exposure is increased four times. Therefore, with short exposures, it is of importance to have the lens of large maximum aperture, at least *f*/6 we should say, and probably *f*/4, since the working stops in the respective cases will be *f*/12 and *f*/8. If you don't mind considerable distance between the negative original and lens, and also between the lens and the sensitive paper, an excellent lens for the purpose would be a cabinet portrait lens of, say, 10 or 12 inches focal length, so that the distance from negative to paper would be from 40 to 48 inches. A portrait lens gives very bright and crisp definition, but as its covering power is very much less than that of other types it is necessary to use a greater focal length.

COPPER TONING.—Kindly let me know following with regard to copper toning for bromides:—(1) Do prints require to be wet before being toned? (2) How long the prints require washing after toning? (3) Does it matter if prints are not free from hypo? (4) Is it suitable for gaslight papers, and if process is a good one? (5) Also if solutions are poisonous either separate or mixed? (6) How long will separate solutions keep (about)? (7) How many prints (half-plate) will 8 ozs. of mixed solution tone?—J. W.

(1) Best to soak for a few minutes before toning. (2) Half an hour is ample. (3) Prints must be perfectly washed from hypo. (4) Prints on almost any gaslight paper will tone well and will yield excellent colours from warm black to red chalk. (5) The chemicals are not dangerous poisons. (6) We think you might keep the separate solutions for at least three months. (7) We cannot say, but should think a dozen or so half-plates in 8 ozs. of mixture.

W. M.—We are afraid we cannot suggest anything to remove the abrasive quality of the cards. Apparently cyanide in the developer does not suit them. You might see whether the use of an acid fixing-bath would do anything to remove the yellow stain, and perhaps, if you could take the trouble, a quick rub over each print with weak iodine-cyanide reducer would clear away the yellowness, although we rather doubt it. No quicker method of glazing than by stripping from glass. If you use one or other of the glazing solutions—Vanguard "Bango," Rajar, or Gem—you will avoid a great deal of the labour of polishing the glasses. The use of a formaline bath makes the print hard enough for using a higher temperature for drying, but, as a rule, the glaze is not so good when the prints are dried very quickly. For practical purposes we do not think the formaline has any bad effect on the cards. Yes, gelatine prints are treated in exactly the same way as collodion prints when glazing with enamel collodion. A burnisher would be too slow for you, and the results are far inferior as regards gloss to those by stripping.

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 3205. Vol. LXVIII. FRIDAY, OCTOBER 7, 1921. Price Fourpence.

Contents.

SUMMARY.

To-day week, Friday, October 14 is the latest date for the receipt of advertisements in the forthcoming British Journal Almanac.

An article, which we are able to reprint from our contemporary, "Conquest," describes with numerous illustrations and examples the photographic methods which are employed in the scientific laboratory attached to the Paris police service. Photographs of finger impressions are used in the detection of suspected persons, and considerable use is made of photographs produced by ultra-violet light for the purpose of detecting fraudulent alterations in documents. (P. 595.)

In a leading article we refer to some of the social opportunities which exist for bringing business to the studio. (P. 594.)

We regret to record the death, at the age of 83, of Mr John Thomson, for many years a leading professional photographer in the West-End of London, and a traveller and inventor. (P. 600.)

In a paragraph on page 593 we give prominence to a misapprehension commonly entertained by clergymen respecting copyright in photographs of churches and church precincts.

Further discussion of plates and film ranges round the alleged absence of halation and the drawbacks of two gelatine surfaces in the negatives. (P. 603.)

In close quarters, a mirror may allow of better drawing being secured of a piece of furniture or of a more suitable lighting being arranged, when photographing a sitter in an ordinary room. (P. 594).

In burning magnesium ribbon in quantity, the best plan is to plait several lengths roughly together. (P. 593.)

The occasional usefulness of hydroquinone as a developer for great contrast, or for the treatment of stale plates or papers, is the subject of a paragraph on page 591.

"COLOUR PHOTOGRAPHY" SUPPLEMENT.

In a contributed article Mr. R. M. Fanstone gives some hints on the making of Autochrome and Paget colour photographs of scenes in autumn foliage, emphasising the advantage of reproducing subjects on a relatively large scale, and instancing the benefit, under difficult conditions of lighting, of giving full exposure and intensifying the plate. (P. 37.)

A hint is given of progress in the Gorsky method of colour cinematography by a recent patent specification describing the process of preparing the three superimposed colour images. (P. 38.)

Particulars are given of the process now being employed by Mr J. Newlands Thomson for the making of two-colour portraits in the studio. (P. 39.)

In the Ulysses process of colour cinematography each picture area receives several partial exposures through the same colour filter for the purpose of avoiding colour fringing. (P. 40.)

Interest is being taken in Germany in a colour process devised by a Herr Loudine. (P. 40.)

EX CATHEDRA.

Almanac, Last Day.

In consequence of contracts made with the printers and binders of the "Almanac" our publishers are obliged to adhere to a date on which they must close their books for the receipt of further advertisements. For the forthcoming 1922 volume, this last day is to-day week, October 14. All advertisements which come to hand on or before this date can be included in the book, and no doubt any advertisement order which arrives at the same time can be executed, providing the "copy" for the printers is available immediately afterwards. On the day following, October 15, the advertisement pages will be finally arranged for the press; while it may be possible at this last hour to find space for an odd page or so, it must be emphasised that it is impossible to guarantee inclusion of advertisers' announcements which reach our publishers later than a week hence.

* * *

Rights in Chuch Photographs.

We are glad to see that the editor of the "Church Times" is able to display a greater knowledge of the law of copyright than is possessed by many of his readers. It is a very common experience of ours to hear from photographers, who have been threatened with all kinds of penalties because they have been publishing views of a church or, sometimes, a churchyard, without the permission of the vicar. We daresay that the incumbent of a church has the right to refuse permission to a photographer to enter the church premises or precincts for the purpose of taking a photograph. But when once a photograph has been obtained, whether with or without permission, the vicar's rights in the matter disappear. He then has no power whatever to restrain the photographer from making any use of the negatives which he thinks fit. Nevertheless, many clergymen seem to hold an entirely contrary and erroneous view.

* * *

Portable Light

There are many occasions on which some form of artificial light is needed, and very often there is some objection to the use of any form of flash light, either because of the risk of firing curtains or other fabrics, or the deposit of white dust. In such cases, magnesium ribbon is a very efficient substitute, requiring no lamp or other appliance besides a clip (to prevent burning the fingers) and a damp cloth or tray to catch any hot ash. The best way to use the ribbon is to plait several strands together, and these may be further secured with a twist or two of very fine flower wire. The advantage of this plan is that not only is the time of exposure reduced, but a continuous light is obtained, for if one strand is extinguished it is immediately relighted by the others. In order to secure good combustion it is necessary that the ribbon has a clean silvery surface, which can be obtained by drawing it once

or twice between a piece of folded emery paper held between thumb and finger. Sharply defined shadows can be avoided by waving the magnesium torch from side to side during exposure. Two or three Swan vestas held together give a good flame for ignition. Wax matches are apt to give a coating of soot, which is an impediment.

* * *

Dark-Room Lamps. The increase of rapidity and colour-sensitiveness which is going on in plate-making renders it necessary to overhaul the illumination of the dark-room if there is any trace of fog upon the negatives. Even the most rapid emulsions of the present day will show no deposit upon the margins protected by the rebate of the slide if the dark-room is properly lighted and reasonable caution exercised in exposing the plate during the filling of the slides and development. It would be well if the old practice of judging the density of the image by repeated inspections, the plate being held close to the lamp, were abandoned. To avoid all temptation, it is an excellent plan to place the lamp in such a position that no direct rays reach the eye of the worker. A comparatively bright light may be used if its rays are reflected from the ceiling or, if this is not convenient, from a sheet of yellow paper fixed on the wall. Once the habit of judging density from the time taken after the image has appeared has been acquired, all desire to toast the negative in front of the red light will cease.

* * *

Negative or Paper? In the far-off days, when wet collodion was practically the only process for obtaining negatives, it was the rule to destroy all unsatisfactory results as soon as developed and to make another exposure forthwith. The principal reason for this was that the albumenised paper then used for printing would not give even passable results from a poor negative, and photographers had perforce to make fairly good ones. Now it is quite different; if there is any sort of image it is deemed good enough to print upon some sort of paper. If we study the advertisements of the various makers of developing papers we find every encouragement given to careless workers, as they are catered for with soft, normal, contrasty, vigorous, and other grades. The carbon and platinum printing processes are not used as often as they might be, because these processes require a negative of good average quality. With a little care it is at least as easy to produce negatives of uniform quality upon gelatine as it was upon collodion, the main points to be observed being uniformity in the strength of solutions and close attention to the time and temperature of the developer.

* * *

A Neglected Developer. Hydroquinone is now rarely used as a developer except in conjunction with metol, but there are many occasions on which its power of giving clear, contrasty images would be of great service, especially as those who compound their own metol-hydroquinone developer have all the necessary materials ready to hand. If sodium carbonate be used as the alkali the developer keeps well in a single solution, although it is better for long keeping to make up the hydroquinone and soda in separate bottles. For line subjects, or when copying from flat originals, great density can be obtained by using caustic soda as the alkali, while the maximum density results from using formaline in place of either alkali. Detailed formulæ will be found in the current B.J. Almanac. Hydroquinone is rather a slow working developer, and should never be used at a lower temperature than 60 degs. Fahr.; 65 degs. is probably the best working temperature, and this should not be exceeded with a caustic alkali. It may not be generally known that hydroquinone is excellent for use with stale plates which give foggy stained negatives with other developers.

* * *

Using a Mirror. Although the interposition of a mirror between the lens and the subject is now almost exclusively utilised for the production of reversed negatives, it has another application, which is very old, but not the less valuable. It is to obtain, in confined situations, a greater working distance, or to secure a more favourable position for the camera. For example, if it be desired to photograph a piece of furniture in an ordinary room where there is insufficient length to allow of the whole being included upon the plate, an ordinary looking-glass may be placed so as to present the image to the lens which is situated at the side of the object. In like manner a portrait may be taken in an ordinary room, and nearly a front lighting secured by placing the mirror in front of or a little to one side of the window, the only precaution necessary being that the camera is not included in the field of the lens. As the angle is usually small, ordinary silvered plate may be used without risk of a double outline. It is, of course, necessary that the mirror does not distort in any way and that it is perfectly upright when straight lines occur in the original.

BUSINESS BUILDING.

Many recently-established photographers find themselves disheartened by the slow growth, or even stagnation, of their businesses, and are inclined to blame the times they live in for what is frequently due to a lack of enterprise or judgment. It is a great mistake to imagine that, given the ability to make good photographs and the premises and plant suitable for their production, all that is necessary is to open the front door and wait for the sitters to walk in. Experience in every branch of industry shows that such is not the case. If we consider the business of the portrait painter who has to reach the same class of customer as the West-End photographer, we shall find that the former either languishes in impecuniosity or that he lets slip no chance of asserting his personality in society. In such a calling as photography, which permeates every stratum of the population, the means adopted to do this must of necessity vary greatly, but the essential idea of making one's professional existence known to as many people as possible must be at the bottom of all. The young painter who has passed through the academy schools with credit, and strikes out for himself, soon finds that he has exhausted the immediate circle of his friends as far as commissions are concerned, and frequently becomes a mere hack to dealers or publishers, earning a pittance which a self-respecting workman would despise. If more astute, he keeps in touch with art circles, and by embracing the newest heresy becomes mentioned in the papers, is welcomed at social gatherings, and finds new ground upon which to exercise his talents in a saner way, all the while taking special care to keep in evidence at every social function to which he can gain the entrée. Although this course is more difficult to the photographer, it has been, and can be, followed with success. Motoring and golf clubs, masonic lodges, musical, philanthropic, and even political organisations all widen the circle of potential sitters, and if the end is never forgotten in pursuing the means, an increase of business must result. It must not,

however, be imagined that this self-advertisement can be dropped when it appears to have served its purpose. We have only to recall the dwindling away of many well-known businesses to realise that it is never safe to rest upon one's laurels until the time for rest has come.

It is not given to all photographers to cut any sort of figure in society, and those who are diffident of their powers in this direction must adopt the methods of the tradesman, rather than those of the artist, to make themselves known; still, the social element must not be ignored, a fair number of provincial photographers become councillors and mayors, and it would be foolish to pretend that these dignities do not react to the possessor's benefit. It is obvious that except in exclusive circles the photographer's business is largely dependent upon his window show as the experience of one amply proved. Business was commenced with no external show, a modest brass plate being the only indication. Little was done, the photographer being unknown in the district. In a few months a small showcase was exhibited, the result being to double the turnover. Later, the premises changed hands, and permission was given to put in a shop window, after which there was no lack of orders.

It is essential that the class of work shown should be acceptable to the residents of the locality. Pictures that command ten guineas a dozen in Victoria Street would not fetch the odd shillings in Tottenham, and this not because the Tottenham folk want poor photographs, but because their tastes run in the direction of small, sharp portraits at a low price. We know of two photographers in the same road in a London working-class suburb. One is just making a living. He is a good artist, his pictures have been hung in the Salon. The other shows the "usual thing" in a style suited to the neighbourhood. He has opened several branches and visits them in an expensive car.

The beginner has no reason for apprehension if he has a reasonable amount of artistic taste and technical ability, together with a modicum of business acumen. A good photographer may open in a locality apparently already overcrowded with photographers and his work will tell, while in a new suburb a man or woman whose work and manners are acceptable to the community will be able to found a business which will grow with the population and defy competition. These are not merely arm-chair opinions, but are based upon recent happenings within our own knowledge.

Specialisation in portraiture has never taken root on this side of the Atlantic; few, if any, of our artists confine themselves exclusively to the pictures of men, children or women, although in the greater American cities the practice has been found satisfactory; possibly a bold "photographer of men" may take the risk of opening in the City of London and achieve success. For some reason which we cannot fathom "home portraiture" is neglected in this country. We have news of one or two workers, little more than amateurs, who are thriving on this class of work, while more experienced photographers sit waiting for days without an order.

We are glad to be able to say that public opinion amongst photographers is strongly against "free sittings" as a means of securing business, some of the oldest offenders in this respect having now seen the error of their ways. It is, of course, sometimes desirable to give "invitation" sittings to celebrities whose portraits are saleable, or for the purpose of securing attractive window specimens, but to do so on the chance of orders from the free proofs is not good business. People who will accept free portraits are not above getting them copied cheaply if more are required; and it is not easy to discover the illegal infringement.

The old practice of having showcases at railway stations and other places of public resort seems to be going out of fashion, except in the outer suburbs. It is difficult to find a reason for this, unless it be the labour incurred in keeping them clean and filled with fresh specimens. Dirty or neglected showcases are worse than useless; they are positively deterrent. To conclude, it is a trite saying, but a true one, that there is no standing still in business; there must be a forward movement or a backward one, and the forward one is only to be maintained by unremitting vigilance and effort.

PHOTOGRAPHIC METHODS OF THE FRENCH POLICE.

[An interesting account of the most recent photographic methods of the Paris police appears in the current (October) issue of our contemporary, "Conquest," the monthly magazine of popular science, of which photography is often a feature. By courtesy of the editor, Mr. Percy W. Harris, we reprint the chief part of this article. Those interested in certain other scientific methods of criminal investigation may consult the pages of "Conquest," where they will find also an illustrated account of the Prizma process of colour cinematography.—Eds. "B.J."]

Often in detective fiction we read of the "polished" criminal, who utilises scientific methods in the prosecution of his evil deeds. It is characteristic of such stories that the police are pictured in a very uncomplimentary manner, the inference being that they have little knowledge of the resources of modern science.

That such a state of affairs no longer exists the reader may rest assured. Rather might we say that the ignorance of science lies mainly with the criminal. We have only to examine the scientific methods of the French police to see what strides have been made during the last fifty years in the detection of crime. As long ago as 1883 the Paris police adopted the system invented by M. Bertillon for the recording and comparison of finger-prints and other personal characteristics. The present "Laboratory of the Scientific Police" is in reality the outcome and extension of M. Bertillon's modest "workshop."

The criminal who has once passed through the hands of the police must be wary indeed if he would avoid leaving at least some trace of his personality on the scene of a further crime. Should he but touch the surface of the furniture with an ungloved hand, the imprints left thereon will render his identification simple. If he has erased a date or altered a cheque, an investigation in the laboratory will reveal the extent of the alteration and the means that have been adopted in so doing. By calling in the aid of the microscope and the analyst it is even possible to tell the material with which a knife or hatchet has been wiped and the substance it has been used to cut. Lately the ultra-violet rays have been brought into play in the detection of crime, while X-rays and the spectroscope are regularly turned to account for such purposes.

Before describing the work of the police laboratory, we will consider for a few moments the preliminary steps taken by the French police in the investigation of a crime. As soon as

the occurrence has been reported to the local police station or to headquarters, a small party of technical experts, consisting of three photographers, a finger-print specialist and a draughtsman, leaves at once for the scene. One investigator examines the lock of the room and carefully notes its condition, while his colleagues photograph the whole of the room and, if the crime be murder, the body. Meanwhile, the

Fig. 1.—The thumb-print of a known malefactor in the records of the police authorities.

draughtsman prepares a plan of the locality and of the room itself. A description, complete in its minutest details, is then made of the body of the victim, its position, the condition of the clothing and anything else which may serve to throw light upon the outrage. Finger-prints left upon smooth surfaces are, of course, a very effective means of identification, since no two human finger-prints show similar patterns. In search of such evidence the investigators must very carefully examine the furniture, window panes, glasses, bottles, papers—in fact, anything which the criminal may have touched. Readily portable objects, such as bottles or glasses, which have finger-prints upon them, are carried back to headquarters, precautions being taken that the finger-prints of the investigators do not touch the surfaces to be examined. Bottles, for instance, are picked up by placing one finger in the neck and the other fingers at the bottom of the bottle, while broken fragments of glass are lifted by their edges. When finger-prints are found on walls, mirrors, or furniture not readily transportable they are powdered over with white lead (if on a black surface) or red lead (if the surface be of light colour),

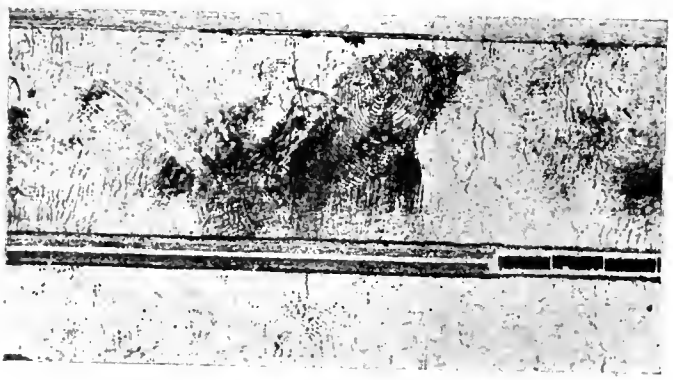

Fig. 2.—The imprint of a thumb on a box. This was proved to be that of the malefactor above. (See Figs. 3 and 4.)

and the excess of powder is removed with a very fine brush. So treated, the finger-prints stand out clearly and are readily photographed.

We will now leave the scene of the crime and see in what manner the scientists utilise the material so collected. Finger-prints, as already indicated, seldom show up well without some treatment, and in the laboratory many clever devices are

Fig. 3.—An enlargement of Fig. 1 with eighteen distinctive markings indicated.

utilised to make them clearly visible. One of these devices is an apparatus consisting of a table of adjustable height, carrying a large camera which itself is adjustable, a powerful

Fig. 4.—An enlargement to the same scale of the thumb-print on the box. The eighteen distinctive markings are easily identified.

electric lamp which can be made to project a beam upon the object photographed, and a holder into which can be clipped objects of practically any shape. To facilitate the examination the holder is made adjustable so that the object may be rotated, raised or lowered without being touched by hand.

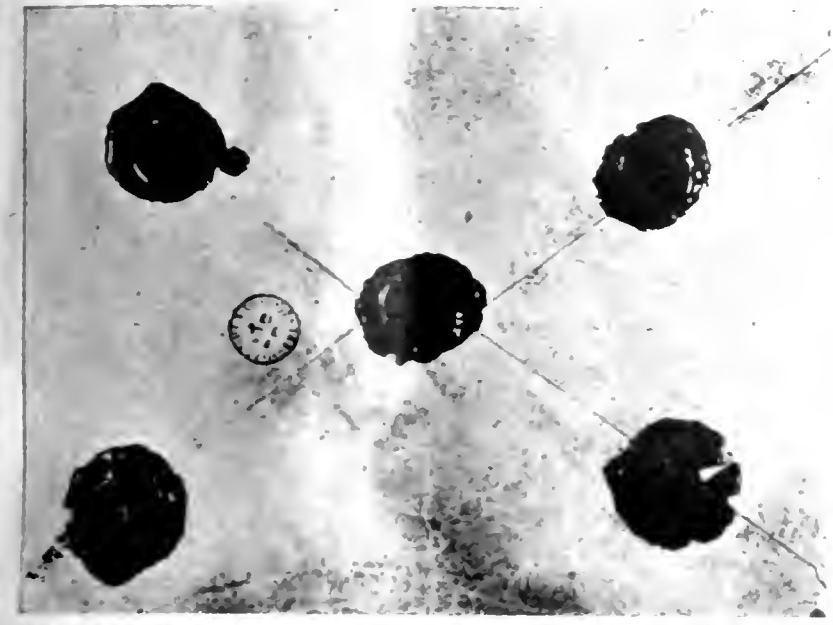

Fig. 5.—This envelope was supposed to contain 25,000 francs. When opened by the addressee it held nothing but wrapping paper! The article tells how the thief was discovered.

It is well-known that many crimes are committed by habitual criminals, who are known to the authorities. Careful records and measurements are made of all criminals passing through the hands of the police, the finger-prints and other evidence being filed for ready reference. Fig. 1, for example, shows the thumb-print of a known malefactor, as shown in the records of the police. In fig. 2 we have a photograph of the imprint of a thumb found upon a small box on the scene of a crime. It was suspected that this finger-print was that of the criminal whose imprint is shown in Fig. 1. How was it proved?

An examination of figs. 3 and 4 soon makes the method clear. Fig. 3 is an enlargement of fig. 1, and fig. 4 a similar enlargement of fig. 2. On these two enlargements are marked eighteen points of resemblance, establishing beyond all doubt the identity of the two imprints.

The official statistics given below prove the importance of the method which last year brought about the identification and final conviction in France of 123 criminals:—

1920.	
Calls upon the special section	1,203
Number of finger-prints collected on the sites of crimes	2,282
Comparisons made	122,205
Total number of negatives developed	4,582
Total number of prints taken	6,788
Criminals traced by means of finger-prints	123

The detection of finger-prints, however, is but one branch of the work of the laboratory. Let us consider another case—that of the envelope with five seals shown in fig. 5. This envelope was supposed to contain banknotes to the value of 25,000 francs, but on being opened by the addressee held nothing but wrapping paper! As the seals seemed to be intact M. Bayle dissolved them in a mixture of benzine and alcohol, and thereupon found that the paper at these points showed no trace of having been torn. From this he argued that the thief had not removed and replaced the seals. Continuing his investigations, M. Bayle immersed the envelope in water so that the whole might be unstuck and opened up as a flat sheet. The envelope was thereupon photographed against the light, as shown in fig. 6. It was then discovered that a portion of the flap was still adhering to the part on which it had been stuck down, indicating that at some time the flap had been torn open after the first gumming down. The presence of a tiny piece of sealing wax on this portion of the paper proved that when the seals were placed on the envelope the tear had already been made. From this, of course, it followed that the theft had taken place in the establishment from which the package had been despatched, and it was shown that the theft actually occurred in the office of a particular employee.

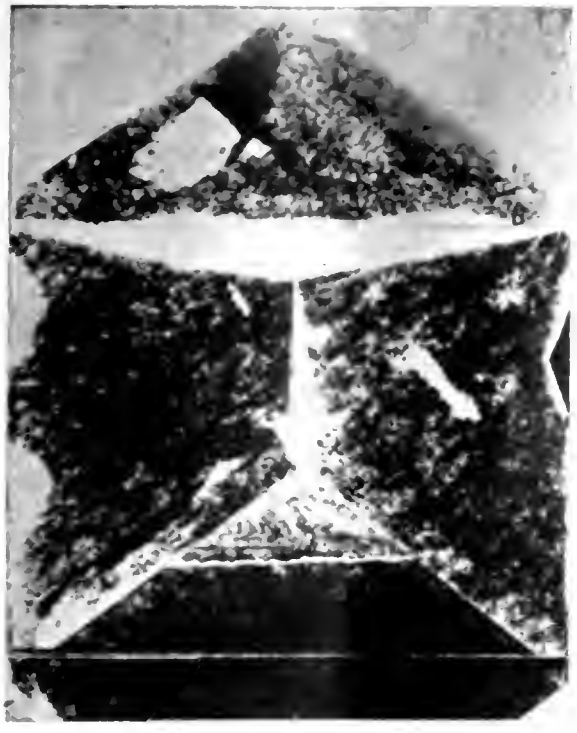

Fig. 6.—The same envelope photographed open and against the light during the investigation. A tell-tale spot of sealing wax gave the key to the mystery.

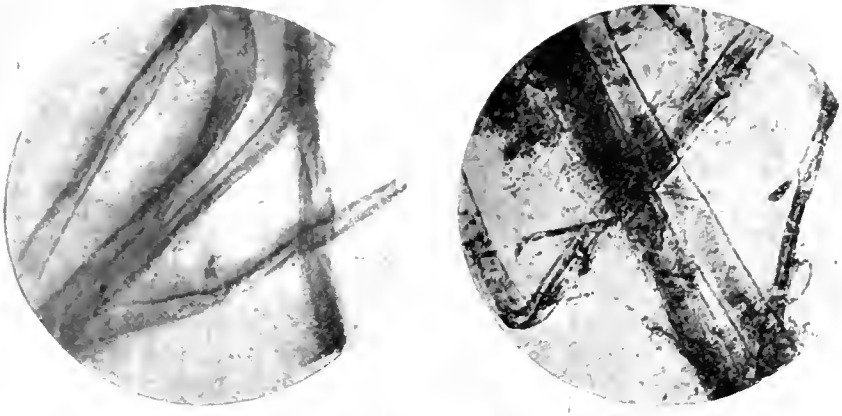
Fig. 7. A suspected hatchet which was shown to have been wiped with a cloth and not with paper.

Photo-micrography is largely used in the police laboratory. On one occasion a prosecutor forwarded the hatchet shown in fig. 7 to the police, asking whether it had been



Figs. 8 and 9.—Fibres of cotton (left) and newspaper (right), magnified 800 times. Those on the left were taken from the rough edge of the hatchet.

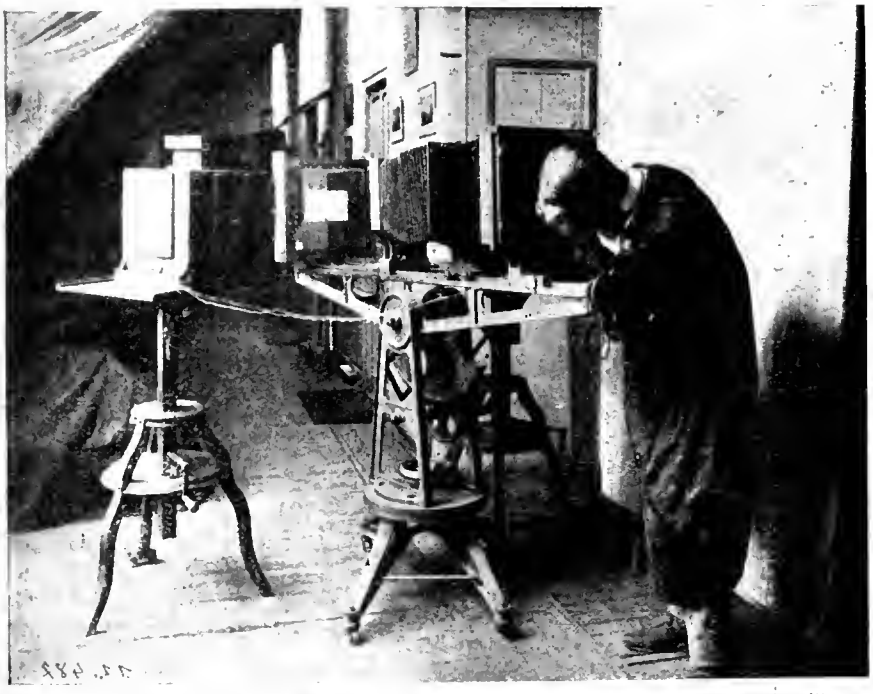


Fig. 10.—Ultra-violet light apparatus used to prove the forgery of the War Bond illustrated in Fig. 11.

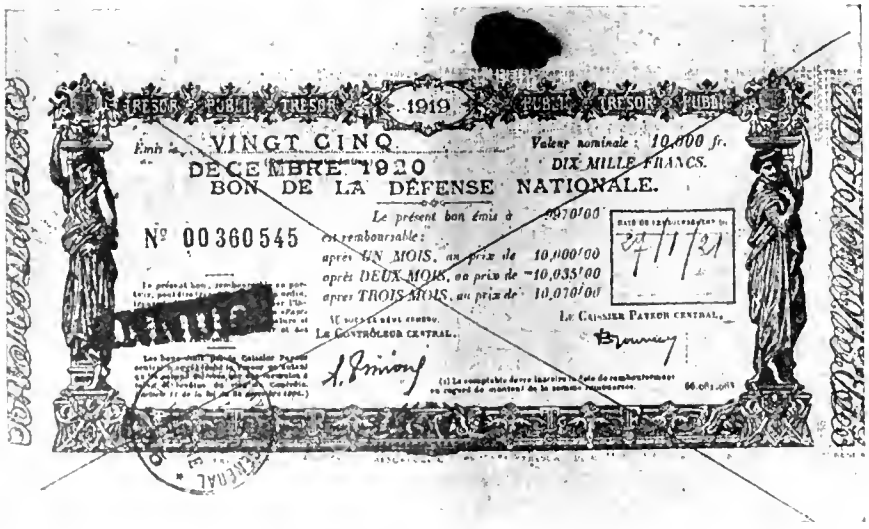

Fig. 11. A French War Bond marked as issued December 25, 1920, and paid on January 27, 1921. Actually this bond had been issued and paid prior to the first date. The forger had erased the original date of issue and substituted a new one. He also removed the date of payment from the small square so that it could be paid a second time.

wiped with a cloth or a piece of newspaper. An examination of the surface with a magnifying glass showed that some specks were adhering to the rough edge of the instrument. These specks were examined under a microscope and proved to be fibrous. When treated with a particular chemical reagent fibres of cotton are stained pink, and those of newspaper (manufactured from wood pulp) yellow. Furthermore, the form of wood pulp fibre is different from that of cotton. This is clearly shown from Figs. 8 and 9, wherein Fig. 8 shows the fibres of cotton found on the hatchet and Fig. 9 those of wood pulp taken from an object wiped with a newspaper. In both cases the fibres are magnified 800 diameters. As rather a large number of the specimens examined showed the characteristics of cotton fibre the conclusion was arrived at that the hatchet had been wiped with a cloth and not with a paper belonging to the suspect. A fact of considerable importance in this particular case, however, was that the stains on the hatchet were shown to be not human blood, as had been suspected, but those of salt pork, for cutting which the hatchet had been used.

In a previous article (CONQUEST, May, 1921, some interesting particulars were given of how X-rays are used to trap the picture forger. Many other obvious uses of the X-ray in the tracking of crime will occur to the reader. Still more interesting, however, is the use of ultra-violet light for the detection of crime. In M. Bayle's laboratory the equipment shown in Figs. 10 and 12 is utilised to examine forgeries of documents. It may be stated here that a photograph of a document taken by ultra-violet light will often reveal details quite invisible in ordinary white light.*

The ultra-violet rays are produced from a specially designed mercury-vapour lamp, the radiation from which is very rich in these rays. The lamp is enclosed in a lantern provided with a special screen opaque to any but the ultra-violet rays (see Fig. 12). The rest of the box is entirely light-tight, so that when other illumination in the room is extinguished the chamber appears completely dark. Actually, however, a beam of ultra-violet light is being projected from the lantern upon the object to be photographed (in Figs. 10 and 12 the object is a French War Bond). Two of these ultra-violet lamps (one on each side of the object) are used.

Some astounding results have already been achieved by means of ultra-violet illumination and photography. As an instance, a large number of French War Bonds were stolen from the French Treasury after they had been paid and cancelled. A forger, using chemicals, removed the handwritten date of payment and the printed date of issue, substituted a new date for the latter, and promptly presented the Bonds for payment. One of the stolen Bonds appears in Fig. 11. From this it will be seen that the Bond is marked as issued on December 25th,

* The relation of the ultra-violet rays to other portions of the spectrum is admirably shown on p. 336 of the June issue of "Conquest."—ED.

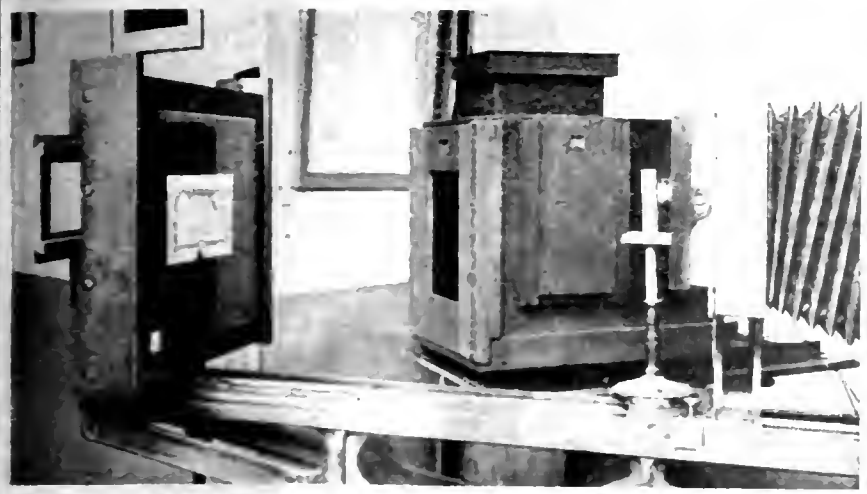

Fig. 12.—A "close-up" view of the ultra-violet lamp box and the Bond mounted for photographing.

Fig. 13.—The photograph by ultra-violet light. Notice how the erased date, "25 Août 20," becomes again visible, although it cannot be seen by ordinary light. This was the original date of payment.

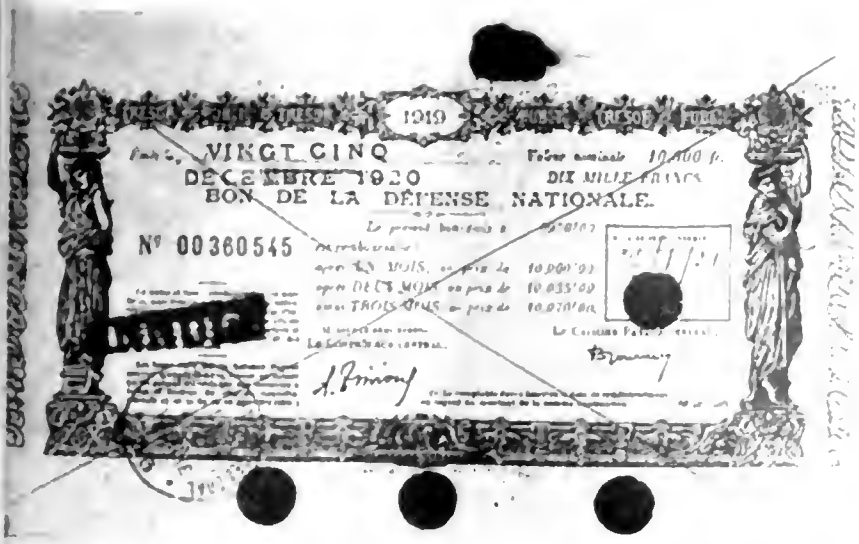

Fig. 14.—Pieces of paper were punched out of the treated and non-treated parts tested with an electrical appliance.

1920 payment being made on January 27th, 1921. The police suspected this Bond to be one of those stolen from the Treasury.

To prove this theory M. Bayle placed the suspected Bond in the holder (Figs. 10 and 12), projected rays of ultra-violet light upon it, and photographed it with the camera. The resulting photograph by ultra-violet light is reproduced in Fig. 13. If the small square-headed "*date de remboursement*" be examined in the two photographs it will be seen that in Fig. 13 the ultra-violet light has shown up very clearly a date—August 25th, 1920 (*25 Août*, 20)—which was quite invisible in ordinary light. It will also be seen that the printed date of issue (*vingt-cinq Décembre*, 1920) disappears in the ultra-violet photograph.

When ultra-violet light falls upon certain substances (for example, sulphate of quinine, nitrate of uranium and certain other salts) these substances become fluorescent, giving off light visible to the eye. In the Bond, practically all the printing and writing was fluorescent. As M. Bayle required to show only those portions of the Bond which were fluorescent under the rays, a special filter was interposed between the lens of the camera and the plate so as to cut off the ultra-violet light and allow only the fluorescent rays to pass through. In this way the result shown in Fig. 13 was obtained.

Having established that the Bond had been fraudulently altered, the laboratory next endeavoured to establish the complicity of the individual at whose house the packet of Bonds had been discovered, particularly as one of his accomplices had been found to be in possession of a pad of blotting paper spotted with chemicals. Was there any connection between these spots and the solution which had served to wash out the ink on the Bond? In other words, had the blotting paper been in contact with the Bonds? The problem presented difficulties insurmountable by ordinary methods, and these were solved by making use of electro-chemical devices.

Students of electricity are well acquainted with the fact that the electrical conductivity of water can be altered by the addition of salts, conductivity increasing with any increase in the quantity of the salt added to the water. M. Bayle possesses highly sensitive electrical apparatus, which enables the slightest variation in resistance of a liquid to be accurately measured. A very high degree of sensitivity is obtained in this apparatus by the employment of a valve amplifier, similar to that used in wireless telegraphy. The apparatus is arranged with a telephone in the circuit so that when a perfect electrical "balance" is obtained no sound whatever is heard. If there is an increase or decrease in the resistance of any portion of the circuit a buzzing will occur. By methods too complicated to be fully described in a popular article this apparatus was used to prove the identity of the liquid on the blotting paper with that used to falsify the Bond.

JACQUES BOYER.

DEATH OF MR. JOHN THOMSON.

We regret to announce the death of Mr. John Thomson, formerly head of the old-established firm of professional photographers in the West-End of London, Messrs. J. A. Thomson. Mr. Thomson died very suddenly from heart failure on Friday last whilst returning from the Royal Societies' Club to his home at Streatham Hill He was 83 years of age.

In the course of his long life Mr. Thomson had keenly followed many literary and scientific pursuits. When little more than a lad he had made enough money by taking photographs in his father's garden in Edinburgh to undertake a tour in China, from which country he returned some years afterwards with many photographs, taken with a home-made camera, and with the material wrote a book, "Through China with a Camera," for which he received a gold medal from Queen Victoria. Afterwards Mr. Thomson took up the manufacture of dry-plates, but his venture was not successful in consequence of the difficulty, in the early days of the dry-plate process, to convert photographers from the use of wet collodion. Mr. Thomson then undertook a second journey in China, and visited many parts of the country not previously explored. He again took a large series of photographs. It was on his return to London that he started a portrait studio in Buckingham Palace Road, removing a few years later to Grosvenor Street, where he remained for twenty-one years, in the course of which time he photographed people of note in this country and from abroad. He was a pioneer in modern studio portraiture, and was one of the first to introduce the pictorial background, which he always painted himself. During his professional life and since his retirement painting and scientific experimental work have occupied his leisure, and we believe that one of his inventions is at the present time awaiting the decision of the Inventions' Commission. The business in which he was so actively engaged for many years is now carried on at 22, Brook Street, London, W., by his son, Mr. J. Newlands Thomson, who for the last few years has devoted himself to colour photography, and of whose work in this field a notice happens to appear on another page of this issue in the "Colour Photography" Supplement.

Patent News.

Process patents—applications and specifications—are treated in "Photo-Mechanical Notes."

Applications, September 19 to 24.

Relief Photographs.—No. 25,333. Means of making sculptures and reliefs from photographs.—E. J. Clifford.

Studio Lighting.—No. 25,096. Artificial lighting accessories for photographic studios. J. W. Freckleton.

Apparatus.—No. 24,916. Photographic apparatus. F. E. Hoffman.

Camera Holder.—No. 25,204. Holder for photographic cameras. A. W. Ker.

Camera Device.—No. 24,744. Camera steadier. J. W. F. Littledale.

Stereoscopy.—No. 24,943. Production of stereoscopic pictures. J. F. Lloyd and Baron A. M. de Ott.

Drying Prints.—No. 24,794. Frames for drying photographic prints. A. L. Price.

Cameras.—No. 25,287. Photographic cameras, etc. G. H. Sutcliffe.

Aerial Cameras.—No. 25,137. Cameras for aerial photography. H. D. Wootton.

Distance Calculator.—No. 25,117. Distance-estimator for photographers. C. E. L. Wright.

Cinematography.—No. 24,937. Optical system for cinematograph projection apparatus. A. C. W. Aldis.

Stereoscopy.—No. 24,967. Stereoscopic photo-projection. A. M. Constant and C. H. Palmer.

COMPLETE SPECIFICATIONS ACCEPTED.

These specifications are obtainable, price 1s. each, post free, from the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C.

The date in brackets is that of application in this country; or abroad, in the case of patents granted under the International Convention.

Colour Cinematography.—No. 100,021 (August 3, 1914). The invention consists in a process of colour cinematography according to which each picture area receives several partial exposures through the same colour-filter.—Pierre Ulysse, Le Val-Pre, Saint Loup, near Marseilles. (Further details are given on another page in the "Colour Photography Supplement.")

Colour Cinematography.—No. 168,100 (April 20, 1920). The invention consists in the making of three-colour transparencies for lantern or cinematograph projection. The positive images from the negative recording the blue-violet sensation are coloured yellow by means of a solution of basic auramine in the presence of basic aluminium acetate. The green-sensation positive is coloured red by means of rhodamine in the presence of acetic acid, and the images corresponding with a yellow-sensation [? red-sensation.—Eds., "B.J."] are toned or coloured blue by treatment with a solution of potassium ferricyanids and ammonia, followed by immersion in solutions of ferric chloride and hypo, and finally of sulphuric acid. Light-filters of methyl-violet 6B, brilliant green and rose-bengal may be used, and the necessity for a protective layer between the component images may be avoided by treating the gelatine film of each image with a hardening solution before the next coating of emulsion is applied. —Serge Michael de Procoudine-Gorsky, The Dell, Croft Road, Sutton, Surrey. (Details of the process are given on another page in the "Colour Photography" Supplement.)

New Materials.

Christmas Card Mounts.—Messrs. Houghtons, Ltd., 88-89, High Holborn, London, W.C.1, send us one of the sample packets of Christmas card mounts which they are offering to professional photographers against remittance of 1s. for the purpose of bringing their season's styles under the notice of portrait studios. The mounts which are included in the collection are all of the folder pattern, and without exception are made of papers of very pleasing light brown, grey, cream, or white papers. Most of them are of postcard size, and provide for the insertion of a postcard print under a cut-out. Some, however, are for prints to be attached within the folder by a touch of adhesive along one edge. The selection is sufficiently varied to represent widely different preferences. Some of the mounts are of the old-fashioned "Christmassy" type, with a certain amount of bright colour, whilst others are in the modern quiet style with relief motto in grey or gold. The prices range from 12s. to 15s. per gross, a reduction being made for three gross and seven gross quantities. The mounts are excellent value, and we have no doubt that Messrs. Houghtons' reminder that orders should be placed at once is necessary in order to obtain delivery of any particular design.

FORTHCOMING EXHIBITIONS.

September 10 to October 8.—London Salon of Photography. Hon. Secretary, London Salon of Photography, 5a, Pall Mall East, London, S.W.1.

September 19 to October 29.—Royal Photographic Society. Secretary, Royal Photographic Society, 36, Russell Square, London, W.C.1.

November 17 to 19.—Bowes Park and District Photographic Society. Particulars from the Hon. Sec., S. Smith, 68, Mannock Road, Wood Green, London, N.22.

December 3 to 17.—Scottish Photographic Circle. Hon. Secretary, W. S. Crocket, 10, Parkgrove Terrace, Tollcross, Glasgow.

1922.

January 21 to February 4.—Partick Camera Club. Particulars from the Hon. Secretary, James Whyte, 51a, Peel Street, Partick, Glasgow.

February 14 to 17.—Exeter Camera Club. Particulars from C. Beauchamp Hall, Hon. Exhibition Secretary, Exeter Camera Club, "St. Denys," Bellevue Road, Exmouth.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

SUNDAY, OCTOBER 9.

Hammersmith (Hampshire House) P.S. Outing to Marlow.

MONDAY, OCTOBER 10.

Bowes Park and Dist. P.S. "Plate Sunk Mounts." J. R. Smith. "Passe Partout Framing." S. Smith.
Bradford Photographic Society. "Pictures of Italian Life." Alex. Keighley, F.R.P.S.
City of London and Cripplegate P.S. Social Evening, musical programme.
South London P.S. "Picture Making in Northern Italy." G. H. Dannatts.
Wallasey Amateur P.S. "Production of a Newspaper." C. Coates

TUESDAY, OCTOBER 11.

Leeds Phot. Soc. Social Evening. Music. Exhibition.
Manchester Amateur Photographic Society. Monthly Meeting.
Morley Photographic Society. Exhibition of Members' Work.
South Glasgow Camera Club. Lantern Slide Monthly Competition.
Tyneside Phot. Soc. "Photographic Lenses." C. J. Young.

WEDNESDAY, OCTOBER 12.

Ilford Phot. Soc. "Camera Portraits with a Portable Light." C. P. Crowther.
Partick Camera Club. "Development of Negatives." A. Dordan Pyke.
South Glasgow Camera Club. "Apparatus and Exposure."
South Suburban P.S. Retouching Demonstration. Robert Coombe

THURSDAY, OCTOBER 13.

Hammersmith (Hampshire House) P.S. "Chartres Cathedral and its Carvings." E. W. Harvey Piper, F.R.I.B.A.
Wimbledon and Dist. C.C. "Faking." M. O. Dell.

CROYDON CAMERA CLUB.

Last week witnessed the opening of the autumn session, following the demise of the informal one which has dealt with varied subjects, not a single Wednesday being reduced to "Conversational," generally signifying the telling of humorous tales, some of reputable kind.

The subject announced for the evening was "Home Portraiture," and the exponent the versatile Mr. A. Dordan Pyke, well known to the club, and an ingennous lecturer who never talks over the heads of the members. Indeed, he is apt to assume the pose of a genial schoolmaster instructing a class of babes and sucklings. This, apparently, is not intended as a special recognition of the mentality of the Croydonians, but doubtless is due to force of habit, for Mr. Pyke discourses airily on many things, in many places, and has to make his themes understood by the veriest beginner.

As a portraitist he is best remembered by a study of Mr. Sellors taken early in the year during a demonstration on flashlight. Advancing towards the sitter, and without any preliminary request to "look pleasant" or anything equally futile, he discharged a flash close to the head of the secretary, whose gasp of astonishment neatly functioned as a trap for descending dust. The portrait was certainly striking, but not one to show an imaginative child subject to nightmares.

Mr. Pyke opened with an apology, as "Home Portraiture," though ready, was not sufficiently so for Croydon, and his discourse, he said, would be entitled "A Story of a Photographer with Two Lenses." In fact, there was no story at all, but merely a set of wholly disconnected lantern-slides, the original negatives having been taken by the "Telecentric" and "Xpres" lenses. Luckily the majority knew that these represented the hall-mark of optical excellence, for the slides, with a few exceptions, most inadequately conveyed this fact. Hardly a good advertisement for the Telecentric, for instance, was an early slide depicting two children on the beach, the negative being so badly under-exposed as to convert their faces into those of niggers.

So obsessed is he with the fear of turning a lecture or demonstration into a "trade" one, commendable up to a certain point, that he gets over this difficulty by avoiding the real subject under consideration so far as possible, only allowing oblique references to it to escape occasionally. However, he jog-trots along in his own gay and festive fashion, and the evening passes pleasantly enough.

In the discussion some members kindly supplied much practical and interesting data relative to lenses in general, and the Telecentric and Xpres in particular, which were very highly spoken of. In reference to the lining of lens-hoods, Mr. Sellors said Dr. Mees many years ago had found that the dead-black paper which undertakers use for lining coffins was the most effective; it had a most depressing effect upon the light entering. A hearty vote of thanks was accorded Mr. Pyke for a discourse which, with alterations and additions, is capable of being worked up to a first-class lecture.

Commercial & Legal Intelligence.

LEGAL NOTICES.—Notice is given of the dissolutions, by mutual consent, of the following partnerships:—(1) Between Arnold Vincent Eckersley and John Edward Norman, carrying on business as portrait and commercial photographers, at 35, High Street, Chatham, Kent, generally under the style of A. T. Honey or A. T. Honey and Co. and occasionally as Norman and Eckersley. All debts due to and owing by the late firm or partnership will be received and paid by Arnold Vincent Eckersley, who will continue to carry on the business at the above address in his own name. (2) Between Lawrence Percival Raven Pritchard, William John Brinkley and Russell Hudson, carrying on business as commercial illustrators and block makers, at 34, Gray's Inn Road, W.C., under the style of The Pritchard Photographic Company. All debts due and owing by the late firm will be received and paid by Lawrence Percival Raven Pritchard and William John Brinkley, who will continue to carry on the business.

NEW COMPANIES.

KINOPOSTERS, LTD.—This private company was registered on September 24, with a capital of £3,000 in £1 shares. Objects: To carry on the business of automatic advertising contractors, photographers, publishers, printers, etc. The directors are: E. L. Smith Masters, Embrook, Wokingham, Berks, and L. W. Blakiston, 67, Broad Street, Reading. Qualification: £100. Secretary: E. L. Smith-Masters. Registered office: 67, Broad Street, Reading.

News and Notes.

LONDON'S FOG FILTER.—The need of artificial light in London studios is obviously very great during foggy days. Describing to the British Association an instrument for recording suspended impurities in the air, Dr. J. S. Owens, of Westminster, said that during a dense London fog there was probably suspended overhead 200 tons of soot. That was the quantity emitted every winter's day from domestic fires between the hours of 6 and 9 a.m.

THE TRAILL TAYLOR LECTURE.—As already announced, the twenty-fourth Traill-Taylor Memorial Lecture will be delivered by M. L. P. Clerc at the house of the Royal Photographic Society, 35, Russell Square, on Tuesday next, October 11, at 7 p.m. The subject of the lecture is "Aerial Photography and Photo-Topography," and M. Clerc will illustrate his discourse with a large number of lantern slides and with a demonstration of stereoscopic lantern projection by the Anaglyph method.

CROYDON CAMERA CLUB.—The redoubtable Mr. Sellors has brought together a formidable programme of fixtures for the meetings of the Croydon Camera Club. During the present month Mr. K. C. D. Hickman will lecture on processes of colour photography, and Mr. Elwin Neame will take a life model to Croydon, and give a demonstration of posing for advertisement photographs; and Mr. Sellors himself, at a later meeting, will demonstrate a method of exposure in bromide printing and enlarging which is both "rational and reliable." The full programme shows that Croydon continues to exhibit a flood of energy, and that its meetings (at 128a, George Street, on Wednesdays, at 8 o'clock) will be as well attended as ever.

THE LATE MR. C. BRANGWYN BARNES.—We are very sorry to hear of the death on September 15, at the age of 64, of Mr. C. Brangwyn Barnes, who had been connected with the photographic profession for the past forty-five years, and had been an occasional contributor to the "British Journal" during almost the whole of this period. Mr. Barnes during the last few years had endured a very painful illness with great fortitude, and up to within a few hours of his death occupied himself with literary work.

200,000 PHOTOGRAPHS PER MINUTE.—Mr. C. Francis Jenkins, of Washington (who was stated in our correspondence columns recently to have been the originator of America's first cinematograph show), has just introduced a new film camera, which, he states, will take 200,000 pictures per minute. The camera is specially made for slowing down and studying (on the screen) the movement of bullets, propellors and other rapidly-moving objects. Pictures taken with this camera slow down normal speed two hundred times, which is to say, an exposure of one second in the camera is extended to two hundred seconds when projected upon a screen. Prisms are used instead of the usual shutter and intermittent movement mechanism.

PHOTOGRAPHIC TRADE'S GOLFING SOCIETY.—A golf club has been formed among members of the photographic trade, and its activities were recently begun by a contest at the Bushey Hall Golf Club between teams captained by Mr. E. W. Houghton and Mr. G. M. Bishop. The following committee has been appointed to make future arrangements:—Messrs. C. S. Downing, D. Geddes and S. S. Bojesen. Information regarding the Society may be obtained from members of the committee, and from the following others who have expressed their intention of joining the Society:—Messrs. A. C. Brookes, W. H. Burditt, P. W. Greenwood, H. W. Hall, Thomas Illingworth, T. M. Illingworth, F. J. Mortimer, H. H. Ward, J. B. B. Wellington and Geoffrey Whitfield.

Correspondence.

*** *We do not undertake responsibility for the opinions expressed by our correspondents.*

BROMIDE PRINTING BOXES.

To the Editors.

Gentlemen,—With reference to the paragraph in the "British Journal" of to-day headed "A Printing Hint," we notice that it is pointed out that the great fault in many printing boxes is a lack of means for controlling the light.

We should like to say that this trouble has been got over by the production of our X.L printer, in which the light can be raised or lowered from the outside of the box so as to allow for the density or weakness of the negative, and with all these machines there is also supplied a ground glass diffuser.

Many of these X.L. printers (which were used by the Army and Air Force during the war) are now being supplied by us to the photographic trade, and, we understand, are giving complete satisfaction.—Yours faithfully,

For and on behalf of F. BRODRICK, LTD.,
C. B. SMITH, director.

50, High Street, London, W.C.2.
September 30.

ACTION OF INSECTS ON GELATINE.

To the Editors.

Gentlemen,—Those who read your article under the above heading in your last week's issue may be interested in the following:—I have had for a number of years portable dark-rooms for use at military camps. As a rule they are built on grassy ground. The earwig is, to my mind, the chief offender. In bygone days I have had negatives utterly ruined by the little brutes, and in consequence I have long since guarded against them by standing the drying racks in a shallow tray of water, so forming a moat around the negatives; the negatives being, of course, raised above the water.

I was surprised only a day or so ago to find a plate with the edges eaten away. I suspected an earwig, and on examining the wooden rack I found one in a crevice I don't suppose it swam the moat, as doubtless it was on the rack when I put it in the water tray.

The designs it executed on the plate led to further designs in the execution business. I would emphatically add: Beware of earwigs.—Faithfully yours,

CHARLES LANE

Maresfield Park, Sussex.
October 3

EXHIBITION V. COMMERCIAL PORTRAITURE.

To the Editors.

Gentlemen,—I am a little bewildered and troubled in mind. I have "done" both the R.P.S. and London Salon shows, read Mr. Tilney's and other learned dissertations on the exhibits, and yet I do not feel satisfied. I cannot quite understand the position of the average portraitist, or what he must do to improve his business. The two big annual shows are unsettling, and are not nearly so useful to the average "bread and butter" photographer as the little show the P.P.A. get together at the Horticultural Hall each spring, and even this little show can—and I hope will—be improved and made of even greater service to those who, like myself, have to make portraits of all comers.

The only picture that keeps well in my mind after making visits to the two shows is "Mrs. M. W.," by Mr. E. Drummond Young, of Edinburgh. Mr. Tilney, in his criticism published in your pages, calls this "one of the most taking portraits . . . a most pleasing result," and most, if not all, professional workers will agree with him. It is the only picture I have seen this year that stimulates me, and the only one I wish to emulate. Between really good professional studio portraiture and exhibition—and High Art if you like—examples, there appears to be a big gap, and pictures made to fill this gap are useless, both artistically and commercially. W. Crooke, W. Thomas, and maybe a few others, appear to get over this gap very well, they producing really artistic portraits commercially (excellent as examples of technique and of exhibition standard, and not out of place in either class or section), but the average worker fails to do so. High Art portraiture, so-called, is to most studio workers a veritable will o' the wisp.

Most exhibition "portraits" are—in a commercial sense—not portraits at all, but fancy, freakish, and theatrical things which would not pay a studio worker to produce, even if he could. And as an example "Portrait of a Lady," by Miss Margrethe Mather (reproduced in the R.P.S. catalogue), may be named. No professional worker would dare to offer a "portrait" of this type to a customer, and to exhibit such a picture in his show-window, would make him the laughing stock of his town; he would be labelled a crank and his business would suffer. Happily the example named is American, and it would be interesting to know what America's new ambassador, Mr. Pirie Macdonald, thinks of it.

The examples of portraiture produced by Mr. C. P. Crowther are perhaps the most talked of pictures of the year, but no professional studio worker, I think, wishes to do work like it, because of its utter uselessness, except, of course, for show purposes. Mr. Crowther's "Showman's Wife" (labelled by one critic as "the picture of the year") would form an excellent attraction for a photographer's window, but I doubt if it would bring him any customers.

About thirty years ago, when I was a lad, I lived in a town where one of the professional workers—Mr. R. H. Lord—made it a rule to exhibit at the (now) Royal Show, and his accepted pictures were always exhibited in his window where they were a great attraction. I never heard that they brought him any business. One, however, never saw the slightest trace of any "exhibition" work in the portraits he produced commercially. The two branches of work were kept quite distinct; had he attempted to combine them he might not have been the successful business man he was.

The novelty, and possibly the charm, of Mr. Crowther's beautiful studies wears off, or becomes very thin, when one studies them very closely and learns of the conditions under which they were made. They are mainly theatrical in reality as well as in appearance, and given such models, whose life is one of posing and expression, most studio workers could produce similar results. Far more skill is required to produce a studio-like—and apparently commercial—portrait like "Mrs. M. W.," or of anyone else not accustomed to posing daily, or of fixing for a time any expression called for. I see, by the way, that Mr. Tilney comments on one exhibited portrait as being "slightly spoilt for me by a kind of actor's excess of muscular mobility about the mouth." The keen artistic eye of Mr. Tilney detected the little defect.

The best professional work, and that of the greatest interest to average studio workers, is to be found exhibited by paper manufacturers on the staircase at the R.P.S. Manufacturers, it is interesting to note, always use technically perfect negatives—good, clean every-day examples of artistic studio (professional) negatives—for producing prints to represent the excellent qualities of their wares, the public never seeing a "faddist" or High Art picture upon a showcard, or in an illustrated advertisement of lenses, plates, and papers, a fact that should encourage and stimulate the photographer who has his living to get.—Yours faithfully,

GODFREY WILSON.

AMERICA'S FIRST "MOVIE SHOW."

To the Editors.

Gentlemen,—Some correspondence has lately appeared in your journal concerning the first exhibition of motion pictures on the screen. The subject has been one discussed a good deal of late, and national prejudices have had some play in the matter.

In the March issue of "Le Photographe," Ernest Coustet gave an outline of the history of the motion picture, leaning too much towards giving France the honours. Apparatus for the purpose of exhibiting apparent motions are of early date, but for the exhibition of pictures obtained by photographing the moving objects themselves, the United States appears to be in the lead. Mr. Jenkins, in his book entitled "Animated Pictures," points out that in 1861 Coleman Sellers, of Philadelphia, took out a patent, No. 31,357, for pictures on an endless band, and Jenkins regards this as the first ever made in a camera, so as to give the appearance of objects in motion.

In 1870 Henry R. Heyl exhibited at the Academy of Music, in Philadelphia, in the course of a lecture given under the auspices of the Franklin Institute, several scenes projected on a screen, using photographs a little over one inch, taken directly from the moving objects. These motions were of a pair of waltzers and some acrobatic performers. The waltzing scene was shown to the accompaniment of appropriate music by an orchestra.—I remain, with respect,

HENRY LEITMANN.

The Franklin Institute, Philadelphia.
September 19.

PLATES v. FILM.

To the Editors.

Gentlemen,—I have followed with much interest the discussion on the relative merits of films and plates arising from Messrs. Kodak's intimation that they are discontinuing the manufacture of plates.

It should always be borne in mind that very few men in any trade or profession see "eye-to-eye," and surely the same thing applies in photography. What one man considers almost his ideal is probably impossible to the next man, and in my mind this applies to the use of plates and films.

Almost from the introduction of Kodak Portrait Film I have used this product, and as I said some time ago in an interview given to the Kodak people, I use film simply because it enables me to make better negatives. Dismissing all question of price and consequent economy of working, and leaving out altogether the weight of outfit and storage in my technical work, I obtain better negatives on film than I have done on plates. And one of the very finest testimonies to the film is the entire absence of that bugbear of technical workers, viz., halation.

My experience is that there is only one branch of photographic work where the plate is preferable to the film, and that is in very high-power photo-micrography, where the plate surface is more likely to carry accurately than the film, for the very slightest warp is fatal to this kind of work.

In conclusion, I cannot but think that the Kodak people have given the very fullest consideration to their policy of the discontinuation of plate manufacture. Such a huge, and in every way prosperous, concern as Messrs. Kodak, Ltd., has not been built up by making foolish mistakes, and, after all, perhaps we shall come to thank this concern for reminding us that we are all liable to become old-fashioned.—Believe me, very truly yours,

SAMUEL GRIMSHAW,
Photographic Department.

Ford Motor Company, Manchester.

To the Editors.

Gentlemen,—In the correspondence on this subject freedom from halation is generally included in the virtues allotted to the film, but, according to my experience, a film halates under exactly the same conditions as an unbacked plate.

The halo is certainly less spread, but more intense in proportion to the thinness of the celluloid.—Yours very faithfully,

EDGAR WARD.

20, Westfields Road, Acton, W.3.
October 1.

To the Editors.

Gentlemen,—In this correspondence I note that several writers consider it quite the thing to introduce a personal note. I consider it is very unprofessional, to say the least. Those who are satisfied that films suit their work better than plates will, of course, continue to use them. Those of us who are not convinced that the good points overcome the bad, will continue to use plates.

Personally, I am not at all convinced that film is of such all-round usefulness to a professional as plates. I am not comparing the emulsions, but the support. The film has three advantages, viz.: Lightness, non-halation, unbreakableness.

For studio work, weight does not matter, and surely breakages are rare? I have not had a negative broken for nearly two years, and only two in four years, so that these two "advantages" can be eliminated entirely. The question of halation is an old one, and has been the subject of countless papers. In this I agree that films score heavily, and for special work where halation is likely to be apparent I should be prepared to use film in preference to bother with backing.

Three parts, or more, of a professional's work is not undertaken under such strong lighting as to cause trouble from halation, neither does the average portrait photographer want to work against the light, or use freak lighting, because his clients would not have it. The fact that one man builds up a reputation on odd effects does not justify others in copying his methods.

I now come to the drawbacks of film, viz., its soft and easily damaged back, its too great flexibility, especially in a humid atmosphere such as we have in Cornwall, and its inflammability.

In my fairly wide experience of twenty-five years I have found it is quite as much as one person can attend to to prevent the *film* of a plate from getting damaged in the various handling which it has to undergo in the average business. To add to that a back which is almost as delicate is asking too much.

We cannot all have baize-covered benches in dark-room and work-room, and we certainly cannot have a staff of careful experts. It takes years to teach the average assistant to care properly for the *face* of a negative, let alone the back.

Apart from that, my own experience was that wherever the air was damp the backs of these films got so tacky they picked up all kinds of dust and dirt on their own account, and the only way to clean them was to put them into water, while a glass plate will stand any amount of cleaning.

My other point of objection is the difficulty of putting work on the back in the way of matt varnish, or dabbing on colour locally.

Someone said it was possible to retouch on *both* sides. Personally I have never wanted to do such a thing. A negative must be a pretty hopeless one if it has to be retouched on both sides; the less retouching there is on the better.

Their flexibility is too apparent in drying; instead of having a few draining racks the rooms would be festooned with dripping films

Then when all these trials and tribulations are over, and the film has passed through the nursery and been packed away, we shall always have a worry at the back of our minds as to what may happen in case of a little flare up in the stock room, or wherever they are stored.

Of course they will not fire unless a light is put to them, and no one would do that wilfully. Still, accidents will happen, and if a flare up occurred in the place a few buckets of water would probably extinguish it if *glass* plates only are stored, but if there are a few thousand films there, it would be a job for the fire brigade and as for sleeping in the same premises with a lot of films stored—no, thanks!

For special work I am not so prejudiced that I should refuse to use films, but for regular work I am sticking to glass plates.—I am, gentlemen, yours faithfully,

ANDREW C. GLOVER.

St. Ives, Cornwall,
October 3.

Answers to Correspondents.

In accordance with our present practice a relatively small space is allotted in each issue to replies to correspondents.

We will answer by post if stamped and addressed envelope is enclosed for reply, 5-cent International Coupon, from readers abroad.

Queries to be answered in the Friday's "Journal" must reach us not later than Tuesday (posted Monday), and should be addressed to the Editors.

O. G.—"The Professional Photographer" is published by Messrs. Kodak, Ltd., Kingsway, London, W.C.2, and "Popular Mechanics" at 239, Fourth Avenue, New York, U.S.A.

E. D.—We are afraid there is no remedy for reticulation produced by the mercury-ammonia process. The most common cause is the use of too strong a solution of mercuric chloride. Also, you should keep all solutions at the same temperature as far as possible. Too strong a solution of ammonia likewise tends in the same direction.

F. B.—Pinholes can be stopped in the blind by means of rubber solution, as used for cycle tyre repairs, mixed with fine vegetable black, but it doesn't make a permanent job. We think it is far better to have a new blind fitted, which you can have done by Messrs. Peeling and Van Neck, Ltd., 4-6, Holborn Circus, London, E.C.1.

L. V.—Non-electric installations for the studio are as follows:—Acetylene: R. J. Moss and Sons, 98, Snow Hill, Birmingham. Gas (incandescent mantles): "Howellite" of Messrs. J. J. Griffin and Sons, Ltd., Kemble Street, Kingsway, London, W.C.2. Incandescent oil lamp: Blanchard Lamps, Ltd., 151, Farringdon Road, London, E.C.1.

M. Q.—There should be no difficulty in substituting half-watt lamps for the mercury vapour tubes as far as the stand is concerned, but as the half-watts require a much greater amount of current it is very doubtful if the wiring would stand it. It would be very wasteful to use a resistance with half-watts. You should procure lamps to work at the full voltage of your local supply. We should advise you to do nothing without consulting an electrician.

E. D.—We have no experience of using an aluminium saucepan for heating up the hypo-alum toning bath, but we don't suppose it would do any harm to the bath. At the same time, we would prefer to bring the bath up to temperature by means of an outer hot-water tank. If you spread out the bath more by putting it in a dish which is contained in an outer vessel of water it would heat up quicker. Messrs. Illingworth supply—or used to supply—an outfit of this pattern.

J. D.—The mirror requires to be of the best optically worked surface, and it would be an entire mistake to attempt to make it yourself. You had far better pay the price of getting a satisfactory one, say, from Messrs. Adam Hilger, Ltd., 75a, Camden Road, London, N.W.1. Focussing is done in exactly the same way as when the mirror is not attached to the lens, the only difference being that you point the camera in one direction and photograph in a direction at right-angles.

H. G.—Every now and then a catatype method of making photographs turns up in the newspapers. The principle of printing by this means was gone into very thoroughly by the Germans some ten or fifteen years ago, and was not then found practicable. Some improvements may have been made, but we doubt it. So far as we know there is no more economical or practical method of making copies than copying the original in the camera on bromide paper. As you say, by using a reversing prism or mirror you can obtain direct copies in white letters on a dark ground. You could, if you liked, avoid the use of a prism by making the copies on Transferrotype paper, and stripping off on to another paper support.

A. J.—The commercial postcard which you send is no doubt from a copy negative on which the titling is done as follows:—A piece of the film in the position shown on the margin of the negative is scraped away and the negative of the lettering applied to it. This negative is made by setting up the lettering in type and photographing a proof; or, of course, the title and number can be written in black ink and likewise photographed. The negative is made on a process plate and stripped off on to the view negative by means of hydrofluoric acid. After transference to this latter, the view negative is blocked out to a rectangular shape leaving uncovered the two areas (number and title) occupied by the subject matter of the title negative.

R. B.—Albumenised paper is now quite unobtainable, at any rate in this country, and we think also in Germany, which previously was the principal producer, but that was 25 or 30 years ago. We dare say you will have some little difficulty in getting a suitable plain paper for albumenising and sensitising. Probably the best thing you can do, if you want to albumenise only small quantities, is to go to a firm which makes various pure papers, such as Olive and Partington, 12-13, Upper Thames Street, London, E.C.4. Probably the makers of raw papers for emulsion coating have not a thin paper which is suitable for albumenising and, moreover, want some persuasion to supply a small quantity. However, you might try them, namely:—Wiggins, Teape and Co., Ltd., 10, Aldgate, London, E.1; Alex. Pirie, Union Mills, Aberdeen. Burton's book gives the most thorough instruction in albumenising and sensitising.

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 3206. Vol. LXVIII. FRIDAY, OCTOBER 14, 1921. Price Fourpence.

Contents.

SUMMARY.

Mr. F. F. Renwick, F.I.C., in an article prompted by the appearance of the second edition of Dr. Lüppo-Cramer's book (referred to on another page of this issue) draws attention to the importance of the chemistry of substances in the colloid state in connection with photographic processes, and stresses the necessity of greater study of photographic problems from this point of view. (P. 607.)

In a recent issue of "La Nature," M. Jean Brizon examines some of the grounds on which the production of pseudo-relief effects in projection are claimed. (P. 608.)

At the Royal Photographic Society on Tuesday evening last, M. L. P. Clerc delivered the Traill Taylor Memorial Lecture, and dealt at length and by the aid of many illustrations with aerial photography and its application to map making. (P. 614.)

At Croydon last week the vagaries of the Bromoil process provided an interesting event. (P. 614.)

The abominable quality of many lantern-slides used for commercial purposes still remains a deterrent from the more extended use of this form of photograph. In a leading article we lay emphasis upon the opportunities which may be cultivated for the supply of lantern transparencies for various descriptions of advertising. (P. 606.)

An active discussion on the place of artistic in commercial portraiture will be found in letters from Messrs. George J. Hughes, F. C. Tilney, and Marcus Adams on pages 618-619.

In the recovery of platinum metal from the spent developing and acid baths in the platinum printing process, the acid clearing solutions must on no account be neglected, since a large proportion of the developer is carried over into them. (P. 605.)

Trial of their suitability for posing purposes, by seating a model in them, is an advisable measure in purchasing chairs for the studio. (P. 606.)

Ample provision in the shape of protection of the camera during outdoor use is a precaution requiring to be taken by those employing their apparatus largely out of doors during the winter season. (P. 606.)

The making of positive prints direct by means of phosphorescent substances and the design of an automatic ferrotype camera are the subject of recent patent specifications. (P. 611.)

A method of increasing the sensitiveness of bitumen to light is described by a contributor to "Photo-Mechanical Notes," where also a recent process for the direct making of half-tone negatives for chromo-litho illustrated. (P. 610.)

A pretty example of judicial wit and acquaintance with the commercial side of the photographic industry is reported on page 612.

The use of self-toning paper for making finger-prints is described by a correspondent. (P. 617.)

EX CATHEDRA.

Posing Chairs. More care is needed in choosing chairs for studio use than might at first thought be imagined. It is not enough that the design should be attractive or that it should be a correct copy of a good antique original; it must be comfortable to the sitter, and its lines and dimensions must lend themselves to graceful posing and correct composition. There are many chairs of which the arms are extremely obtrusive. If the sitter's arm is allowed to rest upon them it is raised too high, making the pose strained and awkward, while if the arm is kept inside the chair the lines of the latter ruin the composition. It is therefore highly desirable for the photographer to be accompanied by a lady model when selecting his studio furniture. Another point which must receive attention is the height of the seat. As a rule, the chairs sold for studio use are too low for any but short people, and give a "bunched up" appearance to tall sitters. One photographer we know got over this difficulty by splicing the legs so as to make them a couple of inches higher. A very useful addition is two or three firmly stuffed cushions with square edges, like a mattress, which can be used to raise the sitter as may be needed.

* * *

Platinum Residues. The continued high price of platinum metal makes it still most important, as a measure of economy, to recover the platinum which passes out of the prints into the developing and clearing baths, for the money which is obtained in this way represents a substantial reduction on the price of platinotype paper. A correspondent reminds us of this by quoting his satisfaction at recently receiving a cheque for £12 for the platinum recovered from the working baths. In this connection it is worth while to emphasise the fact that the acid baths must not be neglected as sources of the precious metal. While theoretically the surplus platinum salt contained in the paper passes into solution in the oxalate developing bath, in practice a very considerable proportion of it finds its way into the first acid clearing bath, and to a much smaller degree in the subsequent clearing solutions. This arises from the fact that the developing solution is carried mechanically into the first clearing bath in considerable proportions. Some recent tests have shown that five whole plate prints, on removal from the developer to the clearer under the ordinary conditions of draining, convey into the acid bath one fluid ounce of the developing solution. It does not require much calculation in order to see that where a number of prints are being handled, the clearing bath very soon becomes a mixture of developer and clearer; and a considerable quantity of the platinum metal will be lost if it is not recovered from the clearing solutions. Those unfamiliar with the method of throwing-down the platinum from the spent baths may obtain an instruction circular from the Platinotype Company.

For the Out-Door Worker. The out-of-doors photographer cannot always choose the weather conditions under which his exposures must be made, and the time of year is now fast approaching when certain precautionary measures should be taken, not only with a view to facilitating successful work under bad conditions, but also that it may be undertaken without risk of damage to the apparatus and as easily as possible for the photographer. One of the greatest difficulties lies in keeping the cloth over the head while focussing, whilst allowing one hand to be sufficiently free to manipulate the rack and pinion. This may be materially assisted by having an elastic loop fitting tightly over the cloth, round the back-frame of the camera. It is then an easy matter, even in a strong wind, to hold the other end of the cloth, while the other hand is quite free. This is a better plan than weighting the corners of the focussing cloth. When photographs have to be taken in the rain, an extra long hood of stiff cardboard, or even an old P.O.P. tube, may be made to serve for the purpose of protecting the lens from rain drops. This will be found of great service, though it can only be employed when the exposure is made with a shutter. Another cause of annoyance is the sinking of the tripod points into the ground, if this is very soft after heavy rain. This may occur so rapidly as seriously to impair the definition while the exposure is being made.

COMMERCIAL LANTERN SLIDES.

Judging from the specimens of advertising slides which form the prelude to many cinematograph performances, particularly in the provinces, it would appear as if the art of slide making had reached its lowest level, as far as professional workers are concerned. The public cannot fail to compare them with the generally excellent quality of the films, and to conclude that the "still" slide is an inherently inferior article. As a rule, the images are harsh and wanting in detail, while the colouring consists of coarse smears of the primaries. This state of things cannot fail to react very prejudicially upon the demand for slides for advertising purposes, as manufacturers who are in the habit of issuing artistic posters and show cards are not likely to spend money upon bad transparencies. This attitude is clearly demonstrated by the fact that most of the slides shown at cinemas are advertisements of local traders, those of the great manufacturers being conspicuous by their absence.

Given slides of good quality, we are convinced that a practically unworked field is open to any enterprising worker, who has the necessary organising instinct and a moderate amount of capital.

Another field would be found in the preparation for shows at the advertisers' own premises or at suitable outdoor positions. For many years a firm of Regent Street photographers displayed portraits of the celebrities of the day and snapshots of current happenings, which formed a perennial attraction to passers by. It would take too much space to go into details as to the nature of the subjects to be shown, but one or two examples may help to make our ideas clear to the reader. At the present season winter clothing is coming forward. Here is an opportunity to show slides of attractive mannequins in fur coats; in the summer, both in London and at the seaside, interesting snapshots would help to sell cameras or film.

This idea is one which may be worked out on any scale from one covering the entire country to one suitable for a small district. If we consider a seaside resort, we have the char-a-bancs proprietors who would probably support a series of views of the show places around, entitled, "Where we take you." The outfitters could show happy children in their eight-and-eleven-penny suits, bathing costumes and caps being another good line, and the photographer himself could demonstrate the quality of his portraits.

There is yet another opening for good slides, namely, as an aid to the commercial traveller or manufacturer's agent. A little while ago the rather ambitious idea of using a portable cinematograph apparatus was exploited, with what success we do not know, but it struck us as being not easily workable. Films are expensive and soon get out of date, but slides can be prepared quickly and cheaply, and the latest goods may be illustrated. As electrical installations are universal the lighting question presents no difficulties, since a focus-type half-watt lamp with adjustable resistance will allow any convenient lamp socket to be utilised, the projector itself being no larger when closed than an ordinary reflex camera.

It is hardly necessary to indicate to a business man the utility of such an installation. At his own headquarters he can show pieces of furniture or machinery in their actual size after the original articles have been sold, while a smaller scale can be employed for displays at the hotel sample room or upon the customers' premises.

Although so many bad slides are to be seen, the production of good ones is not a difficult task, and any decent bromide printer can soon learn the art, which does not differ greatly from the production of paper prints. A rather slow brand of plate is easiest to work and gives the most brilliant results. Unless the negatives have been taken specially, contact printing is not possible, so that some method of reduction is necessary. If daylight be used to illuminate the negative a suitable reflector must be used, and an ordinary swing toilet glass answers the purpose admirably, care being taken that no sash bars in the studio intercept the light. In most cases artificial light will be found most convenient, and an ordinary enlarging lantern affords the readiest means of working, the procedure being the same as for enlarging, with the exception of the substitution of a short focus lens for the ordinary enlarging objective. A very simple way is to remove this altogether and to use an ordinary camera and lens, the latter projecting into the front of the lantern. Absolute sharpness is essential, and to secure this a fairly small aperture, say $f/16$, should be used, except for very dense negatives. Full exposure should be given and a strong well-restrained developer used, the plate maker's formula being usually the most suitable. The occasional worker will, however, find most standard negative developers to work well with the addition of a little bromide solution, as it is essential that there should not be the slightest trace of fog. A test for this is to press the film side of the dry, but uncovered, slide into contact with a piece of white paper, which should be untinted under the highest lights. If there be a slight veil, or if the sky of a landscape be too heavy, the slide may be brightened up by using the iodine cyanide reducer, which does not affect the colour. Thin slides may be strengthened with the chromium intensifier, or if considerable intensification be necessary with mercuric bromide and silver cyanide. It is important that slides should be bone dry before binding up, as any dampness in the film will cause deterioration when the slide is subjected to the heat of the lantern.

The appearance and value of an advertising slide is greatly enhanced by judicious colouring, and for slides which have to stand much work, oil or varnish colours should be used, copal varnish being the most suitable medium. Only transparent colours must be used; such metallic compounds as vermilion, chrome yellow and the ochres appear nearly opaque upon the screen.

COLLOID CHEMISTRY AND PHOTOGRAPHY.

In the part of Essex where I live the water supply is moderately hard, and in certain districts the water has to travel long distances through iron pipes, and often appears of a clear, pale-green colour when run to a depth of 10-12 inches in a white enamel bath; moreover, a bath sponge in the course of a few months assumes a deep brown hue. The green colour of the water is largely due to dissolved iron, probably in the form of ferrous carbonate. A wet sponge, from its highly porous nature, offers an enormous surface to the air, and the iron gets rapidly oxidised to ferric hydroxide which stains the sponge brown. No amount of washing in the water of this district will remove the colour. In the language of colloid chemistry the sponge strongly "adsorbs" colloidal ferric hydrate. When, however, I visited Manchester early last year and took my brown sponge with me, I was at first rather startled on proceeding to use it, to find I was rinsing my face in a coffee-coloured fluid, and thought the mischievous son of the house was up to some prank. It soon became apparent, however, that the sponge was rapidly recovering its pristine pale yellow colour, and after a few days its appearance was nearly normal, but it reverted to its former muddy hue soon after my return home. In this domestic incident we have an excellent illustration of one of the phenomena (adsorption) with which colloid chemistry concerns itself, and which are so common in almost every aspect of photography. Indeed, it is not too much to say that photographic chemistry is more concerned with the chemical behaviour of adsorption complexes than with the more generally understood reactions of ordinary chemistry. This fact is not so well appreciated by British photographers as it deserves to be, and therefore comparatively few have taken the trouble to acquire a knowledge of the elementary principles of that rapidly growing branch of science termed colloid chemistry, which deals with the peculiar effects that result when substances present an enormous surface in proportion to their mass.

The publication of a second edition of Luppo-Cramer's "Kolloid-chemie und Photographie" should not pass unheeded by British photographic chemists, or they will surely wake up one day to realise that they have slept while Germany made progress. Let us consider for a moment a few well-known photographic materials and processes from this point of view.

The difficulty of getting glass, which has once been emulsion-coated, sufficiently free from foreign matter for use a second time was well known to every photographer in the days when the collodion wet plate was the only one available, and during the war when large quantities of old negative glass were returned to the manufacturers for re-coating, it is probable that not a few cases of spoilt negatives were attributable to adsorbed impurities which the cleansing process had failed to remove, while it is certain that the manufacturers had to spend so much time, money, and labour on the problem that many of them regretted having touched it.

Gelatine is a typical colloid, with as many outstanding problems as there are facets to a housefly's eye. Possessing nearly equally-balanced acid and basic characters it is capable of displaying the most diverse properties according to the milieu in which it finds itself. Both in its physical and chemical characteristics it displays a remarkable memory of its previous history, owing partly to its power of adsorbing acids and bases and the hydroxides of the heavier metals, as well as a large variety of organic materials such as dyes, photographic developers, etc., and partly to the fact that solutions of gelatine near the setting point and the gels formed by further cooling possess some sort of complex physical structure which varies with the previous thermal treatment.

Paper again contains at least three, and generally more, colloids, viz.:—Cellulose, resin and alumina, besides dyes and sometimes other materials such as casein, and earthy loadings (for example, kaolin or barium sulphate), all of which present problems to the student of colloid chemistry.

When we turn to the processes employed in the use of photographic materials we are again impressed with the enormous extent to which we are dependent on phenomena of a colloid-chemical character. Print-out emulsions, whether they have been made in gelatine or collodion (another typical colloid), contain silver chloride and citrate in a colloidal condition and the purple photographic image formed during printing consists of colloidal silver. There is also strong evidence for the belief that when we expose a dry plate and form a latent image this latent image likewise consists of an exceedingly fine-grained form of colloidal silver within and upon the surface of the silver bromide grains.

One of the characteristics of all colloids and fine suspensions is that the ultimate particles of which they consist bear electric charges, some colloids carrying a positive and some a negative charge, and when this charge is neutralised the particles are either thrown out of suspension or solution or the characteristics of the solution are markedly modified. These charges can often be neutralised by the addition of opposite charges attached to other atoms or molecules in the form of a solution of a mineral salt or by oppositely charged colloid particles. For instance, an excess of any acid suffices to supply the positively charged hydrogen ions required to precipitate the albumen from white of egg or rubber from the latex, a colloidal solution of alumina or ferric hydrate (positively charged) will form an insoluble adsorption complex with a weak negatively charged gelatine solution. A suspension of fine particles of any kind, which may take weeks to settle, can be precipitated easily and rapidly by analogous methods, as is well known in connection with many systems of water purification. On the other hand, such suspensions, which are often very unstable, can be made extremely durable by the addition of certain colloids such as gum or gelatine. The possibility of preparing photographic emulsions largely depends on the stability conferred on the negatively-charged silver bromide particles by the protective action of the negatively-charged gelatine vehicle.

Other instances in which recent work in the department of colloid chemistry is of great assistance in guiding the experimenter in photography are the numerous applications of dyes, as colour sensitisers, as desensitisers, as toning agents in the mordant process of dye toning, the use of various metallic salts for tanning the gelatine of negatives where it contains a silver image, or again in the study of the causes and the avoidance of discolouration of the gelatine of prints or lantern slides during toning in various solutions, and so on.

It is impossible in a short note to do more than touch upon a few of the colloid-chemical problems which photography offers so abundantly, but there is scarcely a single photographic operation which does not involve the application of some property peculiar to matter in the colloidal state, and photographers will do well to acquaint themselves with the contents of Dr. Lüppo-Cramer's book. For those unacquainted with the elementary principles of colloid chemistry some general reading on the subject is advisable as a preliminary. Those who do not possess a copy of the first edition, published in 1908, should endeavour to procure one, since it covers a wider field than the second edition, which has just appeared, and which is devoted too exclusively to the author's own recent work to be a reliable guide for the general reader.

Many of the experiments he describes are very interesting, and must be accounted for by any satisfactory theories concerning photographic phenomena. It is perhaps necessary, however, to warn readers, since he seldom deals satisfactorily with other workers' views, that Lüppo-Cramer's explanations are not by any means generally accepted.

ingenious and suggestive of further modes of attacking these problems though they often are.

It is, for instance, still an open question how far sensitiveness is due to each or any of the factors—the size of the silver bromide grains, the presence of colloidal silver (amicrons) and gelatine in solid solution in these particles, or to their crystalline structure, and it is still unproved that chemical fog is due to excessive chemical reduction of the silver halide during the "ripening" process. In connection with these matters it is interesting to note his suggestion that certain dyes may produce chemical fog as a consequence of mutual precipitation of a positively charged basic dye and the negatively-charged amicrons of silver in ripened emulsion grains. This is equivalent to the writer's suggestions (see "British Journal of Photography," 1920, July 30, p. 466), with regard to the nature of the development process in general, that charged amicrons of colloidal silver do not, but electrically neutral silver gel particles do, operate as the active germ in development, but Lüppo-Cramer insists that these silver gel particles (see pp. 38, 52 and 53) are always the result of a chemical decomposition of silver bromide by light, catalytically assisted by the dissolved silver amicrons, in spite of the strong evidence that the energy available in the minimum amount of light which can give a developable image is insufficient for the work of splitting asunder one molecule of silver bromide per particle.

Again, Sheppard and Trivelli's recent work on ammonia gas ripening (see their monograph on "The Silver Bromide Grain") throws doubt on Lüppo-Cramer's explanation based on disruption by light of the silver bromide crystals, nor are Lüppo-Cramer's explanations of the phenomena of persulphate reduction or the action of dilute iodide solutions on dry plates by any means generally accepted.

His valuable work on desensitisers is too recent for any generally acceptable explanation to be possible, so that his view, that they act in the light as a mild type of oxidiser inhibiting the separation of bromine, remains an unsupported opinion at present, although some experimental evidence is put forward in its support. His observations on the powerful desensitising action of the old ferrous oxalate developer are particularly interesting as explaining the difficulties in avoiding fog from unsafe dark-room illumination which were encountered during the transition from this to the modern organic developing agents.

Many observations concerning colour-sensitising are recorded, particularly in connection with the influence of the nature of the halide and its fineness of subdivision; these will interest a large number of practical workers. Indeed, all who are engaged in photographic research work will greatly appreciate this second edition, for it will save them much time and trouble in consulting Lüppo-Cramer's very numerous and widely scattered original papers.

F. F. Renwick, A.C.G.I., F.I.C.

PROJECTION SCREENS FOR RELIEF EFFECT IN CINEMATOGRAPHY.

[Of late a great deal of inventive ingenuity has been expended on the making of projection screens for cinematography. In some cases the object is to secure greater brightness of the picture even under conditions of moderate illumination in the projection hall; in others, for the production of a certain measure of relief effect. In his "Paris Notes" of March 11 last, M. L. P. Clerc referred to the Pech projection screen, the feature of which is that it is concave. A relief effect of cinematograph projection on this screen was claimed, but M. Clerc reported that at a demonstration no such effect could be perceived. The question is, however, discussed in the following paper by M. Jean Brizon, in a recent issue of "La Nature," in which the theory is advanced that in the case of an image projected upon a screen which is not a flat surface, the eye endeavours to restore the natural vision, and so obtains a species of relief effect in the projection.—Eds. "B.J."]

In an article recently published in "La Nature," Dr. Pech set forth his explanation of the optical sensation of "relief," *i.e.*, of an impression of three dimensions, obtained by him by means of a screen having a curved surface.

I have studied this question extensively for several years, and I have obtained results which agree perfectly with the very interesting effects described by Dr. Pech. However, I explain these in an entirely different manner.

I was led to take an entirely different view of the matter by the results of the following experiment:—

If two exactly similar positive views on glass, taken from the same negative, are superposed and then examined by transmitted light, the eye will have a tendency to bring forward the first view to the foreground, while relegating the second to the background, thus making a sort of natural selection. This impression is quite unmistakable, of which fact anyone can readily convince himself by experiment; the eye receives an impression of depth in spite of the fact that the identical view is represented upon each of the two plates. The same thing holds true, and the eye continues to make a selection, even when there is only a portion of the view upon the first plate, while the rest of the view is shown on the second plate. Those parts of the foreground borne by the first plate will attract those portions which are shown upon the second plate, and those portions of the background which are represented on the latter will be sufficient to throw to the rear the entire background, and this will hold good *no matter in what manner the image is distributed between the two plates.*

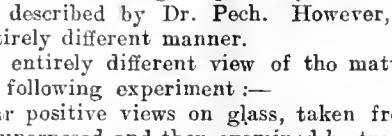

Fig. 1.—A Grating placed before the Screen.

This result, which is not very interesting from a practical point of view, inspired in me nevertheless a lively hope that it might find an application in cinematography. I, therefore, projected views upon screens composed of several planes and found that in all cases, no matter what the scene projected upon the screen, the eye at once made a selection so as to bring the first plane forward; in this manner a quite extraordinary sensation of stereoscopic relief was obtained, a sensation which increased in intensity the greater the separation of the planes of the screen. The screen can be made in various manners; for example, we can place in front of an ordinary screen, at a certain distance from it, a screen in the shape of a grill or grating formed of the elements of the screen (Fig. 1). We can also make use of a single screen having a series of grooves or corrugations as indicated in Fig. 2, which amounts in practice to the same thing as the former. Finally, a very amusing method of producing the screen may consist in making use of the well-known phenomenon of the persistence of vision upon the retina for a certain length of time; this third method enables us to give the spectator a complete and simultaneous view of the image

upon several planes with spaces between them. This method consists in placing in front of an ordinary screen one or more portions of screens to which there has been imparted a rotary movement in a plane parallel to the fixed screen; in Fig. 3 a simple solution of this device is shown in which circular sectors are employed for the first screen.

Unfortunately, and the fact is greatly to be regretted, it is necessary in order to observe the screens, to be as far in front of the front screen as the distance between the extreme planes: this is clearly evident, for when viewed from the side the image is in fact cut or deformed.

The screen employed by Dr. Pech offers a very happy method of obtaining a screen having several planes, since the edges alone of the screen are raised and this so slightly as not to discommode those spectators seated to one side; this curve has been so calculated, on the contrary, as to compensate at least in part for the error of lateral elongation which is the very one which annoys the spectator seated at one side

Fig. 2.—A Corrugated Screen.

when a plane screen is employed. This method, therefore, enables us to profit by a slight separation at the edges, in which location are often found the objects situated in the foreground. We thus obtain a slight impression of depth for these objects; unfortunately, this impression can be proportional merely to the amount of the separation at the margins which is limited in practice.

I hope that Dr. Pech will not bear me a grudge, since my object in saying this is purely scientific—but I am unable to believe that the phenomenon of the distortion of the image upon the retina upon which he bases his theory, plays any part whatever in the case of the present screen. To my mind the proof of this is to be found in the mere fact that the same impression of depth or relief may exist, at any rate so far as the spectator seated in the centre is concerned, with a screen composed of hollows and protuberances arranged at random.

Besides, the well-known fact which Dr. Pech employs as the basis of his theory, namely, that a photograph observed

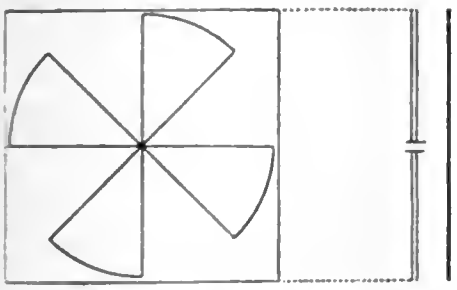

Fig. 3.—The Rotating Screen.

either under a magnifying glass or from a very short distance makes an impression of relief upon the eye, is, in my opinion, due simply to the circumstance that in both cases the observer unconsciously assumes his eye to be in the same position as the lens by which the photograph was made, *i.e.*, subject to the conditions which are involved in perspective. In most cases, indeed, we always look at a photograph from a distance much greater than that of the focal length of the lens used in making the picture. But it is only in case one transports oneself in fancy into the same conditions as those under which the picture was taken, *i.e.* when the eye represents the original lens, that one is able to observe the scene in its natural proportions; in other words, this is possible only when the relative magnitude of the planes is preserved.

In support of this theory I may state that I have made the observation that, so far as moving pictures are concerned, the most definite impression of reality is obtained, when the ordinary screen is employed, by a spectator seated in the centre of the room. The lens commonly used for taking pictures is, in fact, one having a focal length of 50 mm., and the degree of enlargement, which varies, of course, according to the size of the room where the pictures are shown, is about 300 diam. for a 30-m. room. Hence those spectators seated at a distance corresponding to 300 by 0.05—*i.e.*, 15 m. from the screen—are ideally placed to obtain the best results. Furthermore, attention may be called to the fact that when the spectator is too far off from the screen, *e.g.*, at the end of a very large room, the picture on the screen will look as if it were a painting.

The foregoing considerations appear to my mind to support a theory which may be stated as follows: The brain of man seeks always to recover the natural vision of the eye in the artificial images presented to it, and the sort of screen now in question merely lends its aid to this tendency.

In conclusion I may say that I believe it will not be very long before a method will be found—whether by making use of the principles I have just stated, or by means of others, of which it may be easier to make a practical application—to produce a true, but non-binocular, impression of relief in moving pictures.

JEAN BRIZON.

FOX TALBOT MEMORIAL FUND.

As already mentioned in these pages the Royal Photographic Society is establishing a fund for erecting a permanent memorial to William Henry Fox Talbot, to whose researches and experiments the development of photography as we know it to-day is most largely due. Hitherto the English pioneers of photography have gone without any permanent recognition of their work. In France, on the other hand, memorials to both Niepce and Daguerre have been established in several places. In the case of Fox Talbot it is proposed to provide a stained glass window in the church at Lacock, Wiltshire, the little town which for many generations was the home of the Talbots. We are sure that there must be many among the readers of these pages who will wish to contribute to this fund. Contributions are being received by other organisations, including the Royal Photographic Society itself, and we read in the "Revue Française de Photographie" that a sum has already been collected in France, and will be handed over to the Royal Photographic Society in due course. Donations may be sent to the editors of the "British Journal," 24, Wellington Street, Strand, London, W.C.2, and will be acknowledged in this column.

FORTHCOMING EXHIBITIONS.

September 19 to October 29.—Royal Photographic Society. Secretary, Royal Photographic Society, 36, Russell Square, London, W.C.1.

November 17 to 19.—Bowes Park and District Photographic Society. Particulars from the Hon. Sec., S. Smith, 68, Mannock Road, Wood Green, London, N.22.

December 3 to 17.—Scottish Photographic Circle. Hon. Secretary, W. S. Crocket, 10, Parkgrove Terrace, Tolleross, Glasgow.

1922.

January 21 to February 4.—Partick Camera Club. Particulars from the Hon. Secretary, James Whyte, 51a, Peel Street, Partick, Glasgow.

February 14 to 17.—Exeter Camera Club. Particulars from C. Beauchamp Hall, Hon. Exhibition Secretary, Exeter Camera Club, "St. Denys," Bellevue Road, Exmouth.

EARLY BRITISH TRACKWAYS.—In a lecture delivered at Hereford last week Mr. Alfred Watkins gave still another illustration of his intellectual activity and originality. He brought forward a mass of evidence in support of his theory that in this island, long before the Roman invasion, a system of trackways extended in every direction according to a definite geometrical plan. The lecture is published in full in the "Hereford Times" of October 1 last.

Photo-Mechanical Notes.

Half-Tone Chromo Litho.

A RECENT patent specification, No. 146,143 of 1919, granted to L. Bassani, 4, Rue d'Armenonville, Neuilly-sur-Seine, Paris, describes a process for the production of negatives to be used in the reproduction of coloured originals by photo-lithographic and similar methods. The main claim is:—

An improved process for producing from coloured subjects screened photographic negatives intended to be used in chromo-lithography or similar purposes, and in which the screen may be displaced with respect to the negative or sensitive plate, the improved process being characterised by the feature that it consists in producing for each colour two superposable negatives which, by their combination, reproduce the picture exactly in all its shades, the screen being shifted gradually away from the sensitive plate during the exposure of the first negative in a direction parallel to the axis of the photographic camera, and during the exposure of the second negative, the screen being shifted in the same manner as for the first negative, but vertically, these two shiftings being preferably simultaneous.

The invention permits of dispensing with the adjusting or retouching of the screen on the picture by subsequent operations, such as those used in photogravure, and of obtaining the desired result by purely photo-mechanical means. It thus permits of printing

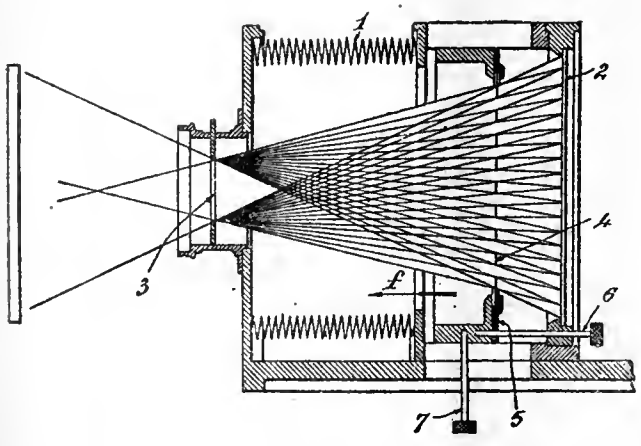

Fig. 1.

directly suitably reticulated photographic plates on to any lithographic surfaces (stones, zinc, and the like), which after being prepared as usual (by inking, gumming, etching, or the like) can be used for printing either by transfer or directly.

By means of the invention, an important economy is thus realised in time and materials. It permits of the use of "offset" machines to the best advantage, and of obtaining on such machines large numbers of prints upon any desired paper, fabric, etc.

The method essentially consists, as above stated, in taking from the original, whatever it may be (water-colour, painting or real subject), for one and the same colour and in identical conditions, two photographic plates which are exactly alike (superposable) and carefully in register with each other.

The first plate is strong, so far as duration of exposure and developing are concerned, so that the thinnest details and the lightest shades of the original will appear. It is produced by arranging a suitable screen in the camera in front of the sensitive plate, and progressively shifting the screen horizontally along the axis of the camera during the exposure.

The second plate is taken under the same conditions, but during the exposure the screen is subjected to an axial and a vertical displacement, both displacements being preferably effected simultaneously.

These displacements, which are independent of the variation in the initial position of the screen, effect, so to speak, a mechanical selection of the parts of the screen that are to be preserved from those that should be reduced or removed

In the drawings, fig. 1 is a vertical section of a camera adapted for use in carrying out the method; figs. 2 and 3 are diagrammatic views showing various positions of the light-rays.

1 is the camera, in which is arranged, between the sensitive plate 2 and diaphragm 3, a suitable stippled or reticulated screen 4 mounted in a frame 5 that can be shifted horizontally along the axis of the camera by turning a micrometric screw 6, and vertically by turning a micrometric screw 7.

Figs. 2 and 3 show on a larger scale the paths of the light-rays in the camera in accordance with the displacements of the screen. Fig. 2 relates to the first photographic plate and fig. 3 to the second.

In taking the first plate which should furnish an image upon which all the details will appear, the screen 4 is shifted, progressively during exposure, by means of the screw 6 in an axial direction as shewn by the arrow *f*. A maximum reduction of the screen is thus obtained even in the lightest shades. Fig. 2 shows, that

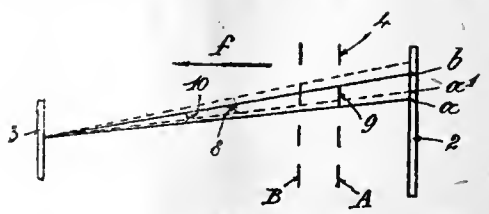

Fig. 2.

when the screen 4 is shifted from position A to position B, the light-beam 10 corresponding to the part 9 of the screen is shifted to the position shown at 8 in dotted lines; so that the unexposed part *a b* of the plate is substantially reduced to *a¹ b*. It will thus be perceived that by a displacement of the screen in an axial direction, as set forth, the screen can be reduced in any desired proportion.

In producing the second plate, which will furnish the dark shades and the junction thereof with the medium shades, the screen during exposure is shifted horizontally by means of the screw 6, and vertically by means of the screw 7. The horizontal displacement has for its purpose to move away the screen as much as necessary for obtaining a sufficiently reduced image of the screen dots so far as the value of the shades is concerned. The vertical displacement has for its purpose to cause the screen image to disappear in all places where required.

Fig. 3 shows that when the screen is shifted from position A¹

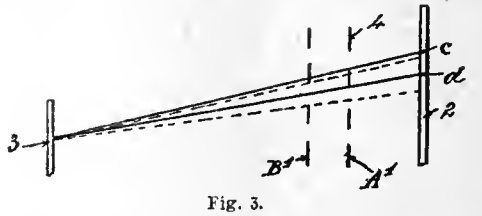

Fig. 3.

to position B¹, the part *c d* of the sensitive plate that was not shielded from the influence of the light-rays by the screen, is subjected in its turn to the action of the rays.

Such displacements may be effected either only once, or several times, according to the effects sought for, or the character of the original to be reproduced.

The reticulated plates obtained are then treated by the usual means, and the images may be transferred by exposure to light on to any printing surface: stone, zinc, etc.

Forcing the Sensitiveness of Bitumen.

THE old bitumen process is not dead. Indeed, I think it may have a useful future before it owing to the growing demand for a photo-zince process on grained zinc plates, which can be printed direct from any good dry plate negative without the intervention of a mechanical screen. The somewhat ancient method of washing bitumen with ether is both messy and costly. Valenta's method of adding a solution of sulphur in carbon bisulphide was an improvement, but the distilling took a long time and is a laboratory job. Seeing that the sensitiveness of bitumen depends on the amount of sulphur present in the compound, I have devised the following way with success. I take two ounces of bitumen powder and melt it in an

aluminium saucepan. When it is in a liquid state I add one ounce of flowers of sulphur and let the whole simmer for a short time, then pour the molten mass into cold water when it will solidify and can be ground to powder, or, instead, pour some turps and make a thick solution for stock to be thinned down with petrol for use. As to development, turpentine is too vigorous and requires much longer exposure, so I use turpentine diluted with petrol, or even petrol alone.

Bitumen takes ink badly alone, so must be reinforced with a little grease. I use a few drops of the well-known photo-transfer ink dissolved first in petrol. Whatever is used it must be first dissolved in the same solvent as the bitumen is dissolved in. Benzole is an ideal solvent for the sensitive bitumen, but is very costly, and unobtainable out here.—W. W. Watt, The Survey Office, Colombo, Ceylon.

The following patents have been applied for:—

Apparatus.—Nos. 24,260, 24,261, 24,262 Photographic copying or printing apparatus for making photo-mechanical printing plates. H. C. Boedicker.

Patent News.

Process patents—applications and specifications—are treated in "Photo-Mechanical Notes."

Applications, September 26 to October 1.

Copying. — No. 25,892. Copying apparatus for photographic pictures. W. Arndt.

View-Finders. — No. 25,820. View-finders for photographic cameras. J. Ascher.

Flash-Light. — No. 25,498. Flash-light photography. E. Chasseranx.

Packing Developers. — No 25,474. Packing photographic developers. J. Gray and T. Teichgräber Akt-Ges.

Photographic Type-Setting.—No. 25,804. Photographic type setting machine. J. Robertson.

Cameras.—No. 25,935. Cameras G. G. B. Tartara.

Exposure Device.—No. 25,495. Controlling exposure in photographic cameras C. M. and S. Williamson.

COMPLETE SPECIFICATIONS ACCEPTED.

These specifications are obtainable, price 1s. each, post free, from the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C.

The date in brackets is that of application in this country; or abroad, in the case of patents granted under the International Convention.

Photographic Copies by Phosphorescence.—No. 160,739 (March 25, 1920). The object of the invention is to produce positive (photographic) copies of letterpress or paper prints by means of phosphorescent substances.

A phosphorescent substance, for instance, Balmain's powder or so-called Sidot-blende, is carefully comminuted. The comminuting is preferably affected by some powder being mixed up with a liquid such as water, and shaken for several hours in a bottle containing glass balls. A very uniform comminuting is effected in this manner. The mixture produced is mixed with a gelatine solution and some glycerine to a suitable consistency, and poured on a glass plate which has been provided with a thin covering of rubber. The gelatine soon solidifies, but before this has taken place a small quantity of the powder has settled to the bottom, and on the surface facing the glass the powder is especially dense and evenly distributed.

After the covering has been dried a solution of celluloid or collodion which has been dyed, for instance red, is poured over and likewise dried. Thereafter the gelatine film and celluloid film together are stripped off the glass plate, which can easily be done owing to the rubber coating, and a red film carrier cover with a phosphorescent layer of specially good qualities is obtained.

This sheet is illuminated, firstly from the gelatine side, for instance, for several minutes by a 100-candle-power lamp, or by daylight, whereby this side is caused to phosphoresce. Thereafter the phosphorescent surface is laid against the picture or printed matter to be copied, and is illuminated by light passing through the red film and through the phosphorescent layer towards the paper. The red illumination will destroy the phosphorescence, and it has been proved that it destroys the phosphorescence, especially where the light strikes and is reflected by the white paper, but in less degree where the light strikes, and is absorbed by the print or the like. After this illumination the phosphorescent plate or sheet is taken off and laid on a light-sensitive paper, for instance, bromide paper, where through phosphorescence it produces a latent positive picture which can be developed in known manner.

Instead of placing the phosphorescent substance in a gelatine film, it may be distributed in a collodion film, and also the coloured layer may consist of some other colloidal substance than nitro cellulose.

If a solid non-flexible plate is desired, both layers can be poured out on a glass plate either on top of each other or one on each side of the same. Also the two layers may be combined into one layer if a dye be added to a phosphorescent substance, so that the phosphorescent layer becomes coloured and acts itself as a light-filter.—Jens Herman Christensen, Villa Sterrehus, Sovejin, Sollerod, Holte, Denmark.

Automatic Ferrotype Cameras.—No. 165,652 (July 7, 1921.) The camera has a magazine chamber immediately above an exposure

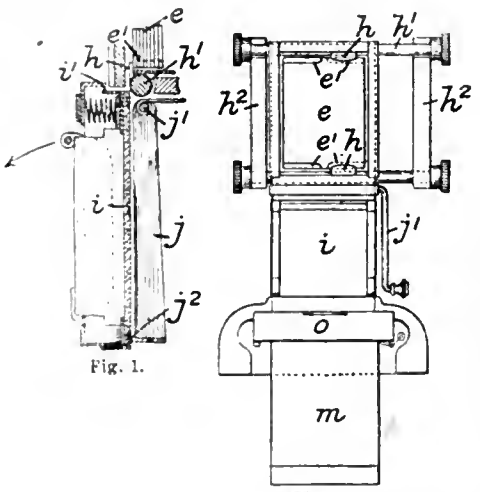

Fig. 1.

Fig. 2.

chamber and a developing tank or tanks underneath. Notched plates are released one at a time from the magazine chamber by laterally displaceable abutments and drop into the exposure chamber from which after exposure they are released and drop into a tank carried by a turntable. The plates e are pressed

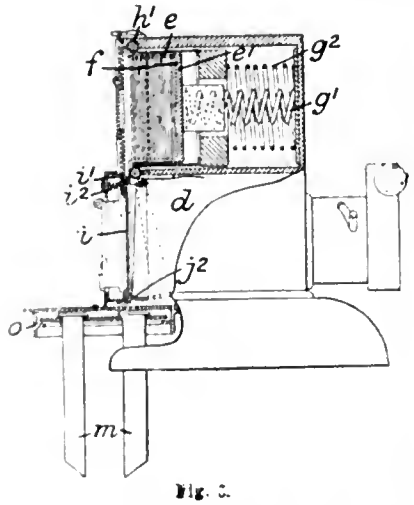

Fig. 3.

forward by a spring g^1 and the pack-holder f is held in position by a spring g^2, the plates being alternately provided with right and left hand notches e^1. The plates are retained in position by lugs h on a frame consisting of rods h^1 and connecting bars h^2,

and are released one at a time by reciprocating the frame. The bars h^2 may be disconnected to allow independent rotation of the rods h^1 and the insertion or withdrawal of the pack and holder f. The end plate e, after it is released from the pack rests upon the upper edge i^1 of a focussing screen i which pivots about its lower border and is retained in position at its upper end by a spring i^2. When the upper end of the screen is withdrawn the plate e falls into position in the exposure chamber d with its lower edge resting upon a lip j^2 on the U-shaped pivoted frame j, the pivot j^1 of which is extended outside the camera to form an operating-lever. After exposure, the U-frame j is turned to release the plate, which drops into one of the developing-tanks m carried by a turntable.—Herbert Edward Hickox, 18, Stanley road, Wimbledon, London, S.W.19.

Trade Names and Marks.

APPLICATIONS FOR REGISTRATION.

ZENITH.—No. 417,425. Chemical substances used in photography, photographic plates and photographic films included in class 1. Ilford, Ltd., Britannia Works, Roden Street, Ilford, Essex, manufacturers of photographic plates, papers and films August 4, 1921.

BAYRAPID.—No. 417,364. Chemical preparations for photographic purposes. Farbenfabriken vorm. Friedr. Bayer and Company, Leverkusen, near Cologne-on-the-Rhine, Germany, manufacturers. July 30, 1921.

MARKS PLACED ON THE REGISTER.

The following marks have been placed on the register:—

TREFOIL DESIGN ("AS DE TREFLE").—No. 415,911. Photographic chemicals, plates and films. Grieshaber Frères & Cie, also trading as Société des Produits Photographiques "As de Trèfle," 27, Rue du Quatre-Septembre, Paris, France, manufacturers, in class 1.

New Materials.

Illingworth Plates, Made by Thomas Illingworth & Co., Ltd., Park Royal, Willesden Junction, London, N.W.10.

FOLLOWING our preliminary note of a week or two ago we must now refer again to the dry-plates, newly issued by them, which Messrs. Illingworth have now added to their well-known manufactures in the shape of printing papers. The firm which takes up the manufacture of dry-plates at the present highly-developed stage of this industry is in the somewhat unenviable position of being compelled to come before the public with goods which are without strikingly novel features. Dry-plate manufacture having reached a high stage of development, the newcomer is doing a great deal if he puts upon the market products which worthily take their place alongside those of other makers. Anything revolutionary in photographic emulsions is hard to find, and, even if found, is of problematical commercial value, as experience during the last few years has shown in several instances. Therefore, a new claimant for photographers' custom in their purchases of dry-plates cannot be expected to do more than show his capacity for supplying the articles which are in constant demand. Such has evidently been the sound policy of Messrs. Illingworth, who, moreover, have the advantage that they are favourably known to great numbers of photographers by the excellence of their bromide, gaslight, and other printing papers. In now offering a full range, with one or two exceptions, of the various descriptions of plate in regular use, they have specially kept before them the requirements of portrait and press photographers, and for these in particular are manufacturing four grades of plate, all of high speed, and in one instance of the orthochromatic kind. Specially for daylight work in the studio, the two grades are the "Studio Fast" and "Studio Extra Fast," respectively issued of speed 400 and 500 H. & D. For use by artificial light the studio plate is the "Studio Ortho Fast" of 400 H. & D., whilst for outdoor work, such as press photography and other purposes calling for minimum exposure and ample contrast, the plate is the "Fleet" of 450 H. & D.

As the result of having taken their time in establishing the manufacture of these and other grades of plate, Messrs. Illingworth have been able to assure themselves of uniformity from batch to batch in speed and other qualities. Moreover, they make a strong point of the fact that the speed markings, while perhaps lower than those of other plates, represent the actual performance of the emulsions as regards sensitiveness. As the result of testing for ourselves the behaviour in practice of several of the grades mentioned above, it is evident that the plates are excellent examples of modern emulsions, fast working without stain or fog, and yielding negatives of extremely fine range of gradation. The developers specially recommended are pyro-soda, pyro-metol, and metol-hydroquinone, but it is clear that the plates afford equally good results with any well-balanced developing formula. On all three of the "Studio" plates ample density is readily secured, whilst the "Fleet" plate yields negatives of the cleanness and brilliance specially desirable in negatives for prints or enlargements intended for reproduction in the press.

Although we have here signalised only the four grades manufactured with the requirements of professional photographers in view, it may be repeated that Messrs. Illingworth are issuing slower grades, including an ordinary plate of fine grain for copying, as well as bromide and gaslight lantern plates. Photographers who have had the occasion to appreciate the good qualities of the firm's printing papers will have no hesitation in accepting the claims which are made for the plates now added to the list of manufactures.

LETO PLATES AND PAPERS.—The Leto Photo Materials Co., Roman Wall House, 1, Crutched Friars, London, E.C.3, send us samples of plates and bromide and gaslight papers, representing new issues of these materials made at their Edgware factory, which, in their original forms, have long been familiar to photographers under the trade mark XL. Among the plates are an ultra-rapid fine-grain emulsion of 400 H. & D., and an improved orthochromatic anti-screen emulsion of the same speed. A pair of plates of somewhat lower speed (350 H. & D.) is also introduced as Leto "Special Rapid" and "Special Rapid A S." We have been exceedingly pleased with the qualities of these plates, which are those of extremely high-grade emulsions. The new or revised introductions likewise include bromide papers of a full range of surfaces for contact printing and enlarging, and also a similar series of gaslight papers, vigorous and soft. A descriptive list of these manufactures has just been issued by the Leto Co., and may be obtained, together with instruction booklets dealing with other of the company's products, free on application.

JUDGES' PHOTOGRAPHS.—In the High Court on Tuesday last a case connected with postcards was being heard. A witness was explaining the superior artistic quality of his, and said they were as good as those made by Judges at Hastings. Mr. Justice McCardie: "Then no doubt they are very good. How much do they charge for them?" Witness: "Threepence each." Mr. Justice McCardie: "That seems a very reasonable sum for photographs made by a judge." Counsel here intervened to explain that Judge was the name of the Hastings firm. Mr. Justice McCardie had a reply pat: "Quite so," he said, "like Jury, the cinematograph people."

CAMERAS IN PUBLIC BUILDINGS.—Mr. Thomas Rodway writes to the "Westminster Gazette": "May I protest against the nonsensical and stringent rule that no cameras are allowed in most of the public buildings of London? There is not the slightest provocation for this rule, and it appears to me to be nothing more or less than a bright idea of somebody's to prevent the public from carrying away a souvenir of their visit to some building. This rule is particularly noticeable at the Tower. Almost half of the visitors to this building carry a Kodak with them with the object of obtaining a photographic record of their visit; but they are disappointed by being relieved of their camera as soon as they enter the gates until they come out again. May I ask, is any damage done to any ancient relic or oil painting, etc., by photographing it? Does it make any depreciation in the value of these? I doubt it.

New Books.

Kolloidchemie und Photographie. By Dr. Luppo-Cramer. 2nd Ed. Dresden: Theodor Steinkopff. Mk. 28.

This second edition is a complete re-writing of the work first published in 1908. In the preface to the latter Dr. Luppo-Cramer urged the importance of studying the properties of the substances which occur in silver-gelatine emulsions and in development. He laid stress on the fact that from the formation and behaviour of silver and silver compounds in the colloid state the extension of precise knowledge of photographic emulsions was to be obtained; and he now looks back with some satisfaction on the fruit which investigation in this field has borne from the work of himself and others. The predominant place which the reactions of colloid substances must have in future photographic research is emphasised by Mr. Renwick in the notes on another page. As these latter deal broadly with the chief controversial questions raised in Dr. Luppo-Cramer's book it will be sufficient here to point out the main divisions of the work.

The author first reviews the properties of metallic silver in the colloid state, drawing here and elsewhere freely from the voluminous researches of Carey Lea. Dr. Luppo-Cramer has collected and published Carey Lea's papers in a German translation and has thus made accessible to his countrymen the results of the American investigator, which have waited for many years to be appreciated at their full significance. In this chapter is discussed the direct reproduction of colours by exposure of silver halides (Farbenanpassung), of which so many hopes have been entertained from the earliest days of photography. The ripening of emulsions and the nature of the latent image provide the subject-matter of two chapters in which these questions are treated in relation to the properties of colloidal silver halides and metallic silver. The chapter on development leads the author to discuss at length his views on the germ or nucleus theory of the latent image, and next, in Chapter VI., the phenomena relating to the development of the more stable part of the latent image, i.e., the process which Luppo-Cramer calls "Keimblosslegung," or "denudation of the latent image germ," as it may be somewhat inadequately rendered into English. The chemical mechanism of optical sensitising and desensitising occupy the two last chapters, which contain a condensed review of the author's experiments which have led to the safranine process.

Throughout, the volume is largely a record of Luppo-Cramer's own work recorded in papers scattered through many periodicals. The personal character of the volume must not be overlooked by the student. Without wishing to say a word in disparagement of much valuable research, it is not possible to escape from the impression that, in the case of Dr. Luppo-Cramer, enthusiasm for a particular explanation appears sometimes to get the better of a cold judicial weighing of the evidence for and against. But as a contribution to the working knowledge of the chemical processes in photography the book is one which must receive the serious study of every experimenter.

Colour Photography.—No. 183 of the "Photo-Miniature," which has just been issued, is a concise review of two-colour and three-colour processes of photography and cinematography from the pen of Dr. C. E. K. Mees. It traces the development of these processes from the fundamental experiments of Clerk Maxwell and the initial practical success of Ives and Miethe. Dr. Mees briefly classifies the methods of making colour screen-plates, and gives an interesting diagram illustrating the rendering of colours by the so-called subtractive process. In comparing two-colour and three-colour methods, reference is made to the satisfactory results obtained by the former system in portraiture. A useful table is given showing the rendering of different colours when the customary two-colour method (recording red and green sensations) is employed. The latter part of the monograph describes processes of colour cinematography which have been commercially employed, namely, Kinemacolor, the Gaumont process of three-colour additive projection and the two-colour process by means of simultaneous optical printing on both sides of a double-coated film worked out in the Eastman laboratory. We miss, however, in this review the Prizma process of printing colour cinema films, the technics of which provide a subject worthy of Dr. Mees's powers of exposition. However, the issue of our little contemporary serves the useful purpose of providing a rapid and accurate glance over the chief methods of colour photography and colour cinematography which have obtained successful commercial application. The issue is published in this country by Messrs. Houghtons, Ltd., price 1s. 8d.; in the United States by Messrs. Tennant & Ward, 103, Park Avenue, New York, price 40 cents.

New Apparatus.

Burst Pipe Stop.—A very handy appliance to have on any premises where water is used has just been put on the market by the Quta Company, 252-254, Haydon's Road, Wimbledon, S.W.19, under the above name. It consists of a pair of metal discs of shallow channel cross section, provided on their concave surfaces with a layer of soft packing, apparently some rubber composition. By means of two screwed bolts the two parts may be fixed firmly in position on a pipe that has burst through frost, etc., forming an efficient preventive of leakage. The appliance is most readily fixed, and in these days when the charge for any little job by a plumber costs a considerable sum, will easily save its price several times over. The appliance is sold, post free, at 1s. 6d.

ROYAL PHOTOGRAPHIC SOCIETY.

Meeting held Tuesday, October 11.

In the absence of the president, Dr. G. H. Rodman, through indisposition, the chair was occupied by Mr. W. L. F. Wastell.

The twenty fourth Traill-Taylor Memorial Lecture was delivered by M. L. P. Clerc, of Paris, who took as his subject, "Aerial Photography and Phototopography."

In first dealing with the apparatus and materials for aerial photography, M. Clerc briefly referred to the alteration in focal length of a lens at the low temperature prevailing at the height of 15,000 or 20,000 feet. He instanced a 21-inch lens, which has its focal length increased by one-half per cent. on cooling from 75 deg. to 0 deg. Fahrenheit. The effect of this elongation is increased by contraction of the body of the camera. A French firm had endeavoured to provide automatic compensation for alteration in focal length with temperature by a special construction of the lens mount.

As regards the importance of light-filters employed in conjunction with panchromatic plates, in aerial photography, M. Clerc described experiments made by the staff of the Eastman Research Laboratory for determining the effects of atmospheric haze. Quantitative measurements of haze were made and various degrees of artificial haze produced in the laboratory for the purpose of testing the efficiency of plates and light-filters in overcoming it. A panchromatic plate exposed through an orange filter, such as the Wratten E, allowed of photography being done through very strong haze.

M. Clerc likewise dealt with the employment of shutters, and mentioned that the focal-plane shutters, almost universally used during the war, were frequently employed at a lessened efficiency in consequence of too great a distance between the blind and the sensitive plate. For exact mapping work the focal-plane shutter could not be used, the movements of a high-speed aeroplane during the period of exposure by the shutter causing deformation errors. On the other hand, the construction of a diaphragm shutter operating at the requisite speed was a difficult mechanical problem. Two French constructors had endeavoured to solve it by giving a constant movement to the sectors of the shutters and bringing in the aid of supplementary sectors by which a particular one of the periodical openings could be selected for the exposure.

In referring to the size and shape of the plate for aerial photography, M. Clerc pointed out that the oblong has several advantages over the square shape of plate. At the end of the war almost all the armies had adopted plates of 18 x 24 cm. size, giving an effective image of 17 x 23 cm. M. Clerc also discussed the relative merits of plates and roll films, the shrinkage of the latter during development, etc., being a drawback in accurate mapping work. Films, moreover, called for special appliances to ensure flatness at the time of exposure.

Contraction of the camera body in consequence of a reduction in temperature of about 75 deg. F., such as is commonly obtained in flights at 15,000 feet, introduced errors of scale and of definition which were serious in phototopographic work. The use of metals and alloys for camera bodies was open to criticism from this point of view, and M. Clerc was inclined to think that the method of camera construction adopted by the Royal Naval Air Service on the suggestions of Mr Charles W. Gamble, was the best for the purpose. For protecting the metal camera body from contraction at the low temperature at a high elevation, the Germans employed electrical heating coils, and a heating envelope for the same purpose was patented by the French Government.

M. Clerc proceeded to deal with the methods and attachments for the production of registration marks on the aerial negative, and for the means of recording on the plates other data, such as compass and altimeter readings. He briefly reviewed, with the aid of a number of lantern illustrations, the various types of camera which had been developed during the war from the original hand-operated model to those providing completely automatic exposure of the sensitive material. Methods of suspending the camera for avoidance of bending or vibration were of great importance. He believed the British Air Force was the first to introduce a method of testing suspension devices by flying over lights on a dark background, one of the lights being periodically interrupted, and thus allowing of the nature of the vibration being recorded on the plate.

He next passed to the consideration of the correction of negatives taken with a non-vertical lens axis and to the interpretation of aerial photographs. In looking at an aerial photograph the best position is that in which the shadows are inclined at an angle of 45 deg. on the right and on the bottom side of the image when the print is held in the hand. A photograph clearly showing the advantage of this method was exhibited. The remaining portion of the discourse was a review of the current methods of mosaic mapping by aerial photographs and the application of aero-photographic methods to surveying. Lastly, M. Clerc outlined the principles of aerial stereoscopic photography, and concluded his lecture by showing a number of stereoscopic projections on the screen by the Anaglyph method, employing for this purpose a number of transparencies and viewing spectacles lent by M. L. Gimpel, of Paris.

On the proposition of Mr. George E. Brown, seconded by Major F. C. V. Laws, the thanks of the Society were accorded to M. Clerc for his lecture.

The chairman, in conveying these thanks, asked M. Clerc's acceptance of the medal annually struck in commemoration of the lecture.

CROYDON CAMERA CLUB.

Mr S. J. Tayler talked, and talked interestingly and instructively on the "Cussedness of Bromoil," that much-discussed printing medium given to the world many years ago by the late Mr. C. Welborne Piper, who later expressed his sincere repentance in metaphorical sackcloth and ashes for the escapade. Some of the soul revelations shown on the club walls from time to time, combined with the ingenious way in which shocked purists endeavoured to fasten a share of the responsibility on the inventor of the process, may have forced him to take up this attitude in sheer self-defence, for he was not a doughty fighter in debate, though ever peacefully content when others were engaged in deadly strife.

In Mr. Tayler's hopeless case additional interest lay in the fact that he is not only a skilful bromoilist, but clever with pencil and brush, for by common consent Bromoil is essentially a process only to be worked by artists, though as all bromoilists apparently regard themselves as such, the reservation does not cut much ice.

He started by saying that although Bromoil is not specifically mentioned in the Book of Genesis, there is no doubt it is included in the primeval curse pronounced on Adam. A few cocksure and brazen spirits pretend to infallibility, but his long experience with the process, if narrated in detail, would deter all contemplating starting on that steep and slippery path. It was paved with disappointment, bewilderment and exasperation, conducing to drink, and terminating, possibly, at the foot of the gallows. (Cheers.) Those, he continued, who had just given robust expression to their feelings, might always be recognised by their cold and calculated cynicism towards pictorial photography in general. Completely absent in their callous breasts was that enthusiasm which first induced amateurs to abandon the cultivation of harmless snapshots in favour of depicting Nature as nobody had ever seen her. He gloried in being one of this nefarious band, for, despite ethical laws, no other process was so alluring, and a bromoilist he expected to be so long as he could handle a brush.

The beginner will find, he said, that all experienced bromoilists are utterly at variance with one another on nearly every practical point of procedure, and flat contradiction is the order of the day. He strongly advised when once a method is arrived at leading to occasional success that it be adhered to, for alterations usually mean starting all over again. He prefers prints on the flat side, employs Kodak's "Permanent" bromide paper mostly, and their special M.Q. developer, and always adjusts exposure to full development. Each print is fixed separately in plain hypo solution to obtain uniform action over the surface (regarded as an important point), and the fixing bath is gradually diluted before the print is removed. In his opinion this reduces any tendency to blisters forming during pigmenting. For the same reason tap-water must never be allowed to fall directly on the prints, which are best individually washed for the first few changes. Surface moisture is to be removed before hanging up to dry, as tear-drops may record themselves in the final picture. When re-soaking papers with soft gelatine a shorter time should be allowed than with hard. Using the water at 75 deg. Fah. an average period is one hour. He had found Sinclair's bleacher very satisfactory, and the pigments supplied by this firm had worked well in his hands

The lecturer concluded by inking-up a bleached bromide print, and a first-class Bromoil eventually materialised with cotton-wool clouds complete (the latter "by request"). Unfortunately blotting paper had been forgotten, and damped brown paper sheets were

substituted. For pressing them into contact an empty whisky bottle proved a capital roller-squeegee, an emergency brain wave of the inventive Mr. Inskeep, who, it is understood, gives the idea freely to the world.

The discussion was brisk, and of the ancient "chestnut" order, Mr. Hibbert in particular distinguishing himself in this line. Another member pointed out that having regard to the successful picture secured, the prefix "cussedness" adopted had proved singularly inappropriate. "Quite the contrary, for under the conditions I confidently anticipated nothing but failure" replied Mr. Taylor.

EDINBURGH SOCIETY OF PROFESSIONAL PHOTOGRAPHERS.

Meeting held at 116, Hanover Street, Edinburgh, on Monday, October 3. Present: Messrs. Aikman, Norman Thomson, John Campbell Harper, W. J. Hutchison, George Balmain, Yerbury, E. D. Young, Swan Watson, William Fergusson, John Thomson and Charles Ross. Mr. J. Campbell Harper, president, in the chair.

The Secretary read a letter from Mr. W. B. Hislop, of the Process Engravers' Federation, who had been invited to the meeting, regretting his inability to be present. The Secretary stated that Mr. Hislop, who has undertaken the tuition of the class for optics and chemistry as applied to photography, inaugurated by the Education Authority, intimated that he had sixteen students at the class last week, and that he expected to have twenty-four this week. This was considered very satisfactory.

Mr. E. D. Young mentioned that the College of Art classes commenced on Wednesday, October 5, and that the College officials were to notify photographers in Edinburgh of the commencement of these classes and ask them to get their assistants to attend. The Society recommended its members to do their utmost to get their assistants to attend these training classes, so that better results might be obtained by the students in their work in the studio.

The meeting next considered the fixing of minimum prices for commercial photography. The Secretary submitted to the meeting the prices which were originally fixed and those which were afterwards substituted therefor, also the proposed costing basis table with a percentage of profit added proposed by Mr. Moffat. After considerable discussion it was resolved to allow matters to lie in abeyance for another month until the minimum prices fixed by the Process Engravers' Federation were ascertained, so that both societies might co-operate and fix a similar basis of minimum prices. It was agreed that members might meantime use either of the latter charges, whichever they considered suitable for their work. It was also agreed to invite Mr. Hislop to the next meeting of the Society and get the benefit of his views before fixing the minimum prices.

Mr. Balmain intimated that the golf match with the Glasgow Professional Photographers would take place at Turnhouse on Friday, October 21. There would be twelve players from each society, and the play would be in two-ball foursomes. It was agreed to entertain the Glasgow photographers at dinner at the Haymarket Restaurant in the evening.

After the conclusion of the business of the meeting the new president, as is customary on his assuming the chair at the first meeting after election, made a few cogent remarks about the Society, the responsibility of its members and duties to professional brother photographers. He gave an interesting retrospect of his early career in business and of his attitude towards his professional brethren. He gratefully acknowledged that by his personal association with them in business and in a society such as this his opinions had entirely changed, and from considering them as rivals he now found them friendly competitors. He urged the members to become progressive and keep in touch with things if they desired to go forward with the times, as it was the photographer who is able to show a personal and distinctive character in his work who will get work. He earnestly commended the members to endeavour to stimulate and foster a knowledge of art as applied to photography among their assistants so that the photography business may in the future be carried forward to greater progress and expansion on a stable basis.

Mr E. D. Young, in moving a vote of thanks to the president, congratulated him on his remarks and wished him a long and prosperous period as president of the Society.

Mr. Swan Watson associated himself with Mr. Young's remarks and said that he was confident that the Society would flourish under Mr. Campell Harper's guidance.

The President returned thanks and asked the members to co-operate with him and each other in the promotion of the best interests of the Society and for their profession.

LANCASHIRE SOCIETY OF MASTER PHOTOGRAPHERS.

The third annual meeting was held at the Palatine Hotel, Blackpool, on Wednesday, October 5, 1921. Mr. Fred. Read, president, in the chair.

Mr. Charles Howell, on a point arising out of the Minutes, informed the members that the letter written by the secretary with regard to the electric supply in one of the towns in which he had a studio, had been the means of him getting a reduction of £25 from his account, and, in addition to this, he had received a very important concession, viz.: "That in future he would only be charged power-rate," whereas, in the past he had been charged on the lighting rate for all his electric energy. In his opinion many photographers failed to recognise the advantage of being a member of the Society, and he hoped in the future that more progress would be made in that direction.

Mr. W. T. Carter, of Rochdale, also gave testimony to the advantages he had received by being a member of the Society, as he also had received a very considerable concession from the authorities in his town. Other matters arising out of the Minutes having been dealt with, the president, Mr. Fred Read, rising to give his address before he left the chair, thanked those members who were present for their kind co-operation during his year of office. He regretted, however, that during the period he had occupied the chair, there had been a number of factors, such as labour troubles, bad trade, which had prevented members from attending meetings. He regretted to have to admit also that a number of the photographers who had joined the Society, had not since its inception given the support that he had expected. There was a great deal of apathy amongst the members, and if they would only take to heart the experiences of Messrs. Howell and Carter and other members and compare testimony to the advantages they had gained by being members of the trade Society, he hoped his successor in office would have a better year than he had had.

The committee had unanimously recommended as his successor, Mr. Arthur Winter, of Preston, and it afforded him very great pleasure in proposing Mr. Winter as president of the Society. Mr. Gresswell, of Southport, seconded this proposition, and was supported by other members. Mr. Winter was unanimously elected, and was inducted into the chair by Mr. Fred Read. Mr. W. T. Carter (Rochdale) proposed that the vice-president be Mr. Charles Howell, of Blackpool. This proposal was seconded by Mr. J. S. Browne (Manchester), supported by Messrs. Read, Berry, and Huish, and carried unanimously.

Mr. Fred. Read, in proposing Mr. W. T. Carter as the hon. treasurer, stated that the committee has unanimously elected Mr. W. T. Carter for this position, and he sincerely hoped that at the end of Mr. Carter's year of office he will have had greater success than his predecessors, and those hon. treasurers, including himself, who had occupied that position. Mr. Berry (Rochdale) seconded this proposition, and Mr Carter was unanimously elected as hon. treasurer.

Mr. J. S. Browne (Manchester) proposed that Mr. W. H. Huish be re-elected as secretary, and stated that his only object in doing so was to give that gentleman an opportunity to maintain his reputation. This proposal was seconded by Mr. Gresswell, supported by several members, and carried unanimously.

Mr. Huish, in thanking the members for the renewal of their confidence, stated that he had intentions of seceding the election, but in consequence of his good friend, Mr. A. Winter having been elected as president, he had no alternative but to accept the position.

A lengthy discussion took place on the question of the election of a committee. In consequence of a number of members who were appointed last year not having attended, it was decided only to elect members on the committee who had taken an interest in the work of the Society. Mr. Read proposed that the following gentlemen represent the committee:—Messrs. A. Walmsley (Bolton), Cyril Foley (Wigan), W. H. Baylis (Chorlton-cum-Hardy), R. H. Gress-

well (Southport), W. P. Beck (Blackpool), E. J. Care (Eccles), J. S. Browne (Manchester), J. W. Berry (Rochdale), Dor Maclean (Blackpool). This proposal was seconded by Mr. W. H. Huish, and carried unanimously.

The hon. treasurer's statement of accounts was received and adopted, and showed a credit balance of £22 15s. 9d. It was proposed by Mr. Carter, and seconded by Mr. Gresswell, who had acted as auditors, that the best thanks be given to Mr. Arthur Winter for the admirable way in which the accounts had been kept and presented.

Mr. W. H. Huish stated that at the last committee meeting the president, Mr. Fred. Read, had referred to the apathy that had been displayed by many members of the Society, and it was reported that at that time sixty-seven members had not paid their subscriptions for the current year. He (Mr. Huish), therefore, considered that the time had arrived when the members should consider very carefully the re-construction of the Society. He would suggest for consideration that a limit be put on the number of members, so that those who were loyal to the Society would benefit most. He would like to make it difficult for photographers to become members of the Society, and he saw no reason why they should not have a "waiting list," the same as other exclusive societies. He advised that the membership be limited to 100, and that in future only four general meetings of the Society should be held during the year, and that at these meetings arrangements should be made for some expert to give a lecture or demonstration that would be of interest to the professional photographer. After a very lengthy discussion Mr. Gresswell proposed that the suggestions outlined by Mr. W. H. Huish should be carefully considered by the new committee, and it should be in their power to draft new rules and make all the necessary arrangements for the year's working. This proposal was seconded by Mr. Berry, supported by other members, and carried unanimously.

At the conclusion of the business meeting, Mr. Arthur Winter, the new president, entertained the members to dinner, and a very pleasant evening was the result.

GLASGOW AND WEST OF SCOTLAND SOCIETY OF PROFESSIONAL PHOTOGRAPHERS.

The annual meeting of the above Society was held on Friday, September 30, 1921. The Vice-President occupied the chair in the absence of the President, Mr. J. G. Mainds. Mr. Weir opened the meeting, expressing regret that owing to illness Mr. Mainds was unable to be present, and suggested that the Secretary convey meeting's sympathy and appreciation of his services during the past year.

The Chairman gave a *résumé* of the year's work, and said the Society had reason to feel gratified by the number of interesting lectures and demonstrations which had been given, and expressing the Society's indebtedness to Messrs. Kodak, Ltd., the President, Mr. Drummond Young, Mr. Allan Mainds, Mr. Weir and Mr. Polmont for their lectures and demonstrations, and to Messrs. Brinkley, Fairbairn and Mainds for the use of their studios.

The social event of the year took the form of a smoking concert, which was a great success, the talent being of exceptional merit.

A report on the committee's negotiations with the Glasgow School of Art re classes in photography was submitted, and it was regretted that owing to the small response the class intended to be started in September was unable to be gone on with, but when the advantages of the classes are more fully realised among employers and assistants a better response is expected, which will enable a start to be made early in the coming year.

The Secretary submitted the financial statement for the past year, which showed a credit balance, notwithstanding the period covered being 18 months, the adoption of which was duly moved and seconded.

A vote of thanks was proposed by the Chairman to Mr. Romney, junr., for the very capable manner in which he had discharged the duties of secretary and treasurer, which had contributed so much to the success of the Society in its first year. The meeting then proceeded to elect the following new office-bearers: President, Mr. J. R. Brinkley; vice-president, Mr. A. Fairbairn; committee, Messrs. Nimmo, Romney, junr., McGregor, Ritchie, Doig Polmont, McCracken, Shankland, Q. R. Whyte, MacLachlan, Donaldson and Phillips. Secretary and treasurer—Mr. Romney, junr., kindly agreed to carry on the duties until the vacancy could be filled.

The new president, on taking the chair, thanked the members for the honour they had done him and assured them he would do all he could in furthering the interests of the Society, and intimated he had approached Messrs. Kodak, Ltd., who had kindly consented to allow Mr. Luboshez to give a lecture and demonstration on artistic lighting.

This completed the business of the evening, and the Chairman, in closing the meeting, thanked Mr. Weir for occupying the chair during the early part of the evening. The next meeting of the Society will be held in Mr. Brinkley's studio, 230, Sanchiehall Street, on Thursday, October 27, at 7 p.m., when Mr. Luboshez will lecture and demonstrate on artistic lighting. This meeting will not be confined to members of the Society, and an invitation is extended to all principals and managers in the profession.

Commercial & Legal Intelligence.

NEW COMPANIES.

Lincoln Studio, Ltd.—This private company was registered on October 1 with a capital of £1,000 in £1 shares. Objects: To acquire the business carried on at 148 and 149, Holborn Bars, E.C., as "Isograph and Rudos Camera Service," and to carry on the business of atists, designers, photographers, advertisement agents and writers, art exhibitors, art gallery and exhibition proprietors, cinematographers, etc. The first directors are: S. P. Dobbs, 8, Shaftesbury Avenue, New Barnet, artist; Mrs. R. Dobbs, 8, Shaftesbury Avenue, New Barnet; A. R. Crouch, Redcot, 1, Rutland Road, Wanstead, Essex, artist. Registered office: 148 and 149, Holborn, E.C.

Lloyd and Ramsden, Ltd.—This private company was registered on October 4 with a capital of £3,000 in £1 shares. Objects: To take over the business of manufacturers of cinematograph projectors and general electricians carried on at 17 and 19, St. Michael's Street, Nottingham, as "Lloyd and Ramsden," and to carry on the business of manufacturers of cameras and parts thereof, film manufacturers and renters, photographers, etc. The first directors are:—E. G. Lloyd (permanent managing director), 4, Friar Yard, Nottingham; Capt. O. W. Redgate, Inglenook, East Leake, Notts.; C. E. Ramsden, 10, Wilford Grove, Nottingham. Qualification: £100. Remuneration of managing director: £400 per annum; of other directors, as fixed by the company. Registered office: 17, St. Michael's Street, Nottingham.

A Link with the Past.—The name of Dollond has been an honoured one in the optical and photographic world for generations, and the death of Mrs. Fanny Dollond at her home in Streatham a few days ago removed the last direct descendant of John Dollond, the eminent English optician of the eighteenth century

Family History Photography.—The making of a series of weekly or monthly portraits of babies is no new thing among amateur photographers (writes a correspondent), and one wishes it were more common in the studio, and that parents could be persuaded to bring their children more often. It might, by the way, be a good thing for professional workers to advertise and make a specialty of, say, monthly portraits of newly-arrived babies. Cinematograph producers have, it appears, opened up a new branch of work, for last week's newspapers stated that a firm of film producers are at present busily engaged in making films for private families. These films range from 300 to 1,000 feet and upwards in length and form a permanent record of families' histories. Supposing the family came over at the time of William the Conqueror, their cinematographic tree may commence then, the characters of their ancestors, of course, being enacted by living members of the present generation, and the history brought right up to date to the first tottering footsteps of the latest baby. The continuation of the film by additional scenes, when opportunities occur, will enable the present heads of the family—say, on the occasion of their golden wedding—to enjoy an entertainment harking back through the dim years to their happy childhood and subsequent marriage. There is, we are told, a wonderful field for this new method of recording family history.

News and Notes.

R.P.S. Pictorial Group.—On Thursday next, October 20, at 8 p.m., Mr. George Clausen, R.A., will deliver an address. Members of the Group are asked to note the special interest of the occasion.

Missing Overcoat.—The gentleman who by mistake took a green-grey waterproof coat after the lecture at the Royal Photographic Society on Tuesday evening last is requested to communicate with the secretary.

A Compact Camera.—Among the latest American inventions is a camera which can be built up cheaply of cardboard or other sheet material, cut in blank form in such a manner that it may be folded flat to remain convenient for carrying until required for use, when it may be formed into a temporary camera by joining the edges with flexible gummed binding strips. The camera is so constructed as to use daylight-loading photographic film packs. The patentee is N. E. Brown, of Grand Haven, Mich.

Wray Lenses.—Messrs. Wray, Ltd., Ashgrove Road, Bromley, Kent, send us the descriptive price list, newly issued, of their photographic lenses and other optical instruments. Their series of objectives includes the "Lustrar" lenses of *f*/4.5, *f*/6.3 and *f*/8 aperture, casket anastigmats, wide angle and cinematograph lenses and those of the Petzval portrait type. The catalogue contains particulars and prices of cameras fitted with these lenses, and is obtainable free on application to Messrs. Wray.

Kodak £1,000 Competition.—Messrs. Kodak, Ltd., have organised a competition to run from the present month until March next for prints or enlargements by amateurs, in which altogether £1,000 will be awarded in prizes. The results may be made with cameras and materials of any make, not necessarily those of the Kodak Company. The competition will be advertised largely in the provincial press, and circulars giving full particulars may be obtained from all agents for Kodak goods.

Messrs. Taylor, Taylor & Hobson, Ltd., announce that their sales department has been transferred from Leicester to 74, Newman St., London, W.1. Correspondence relating to orders and all other commercial matters will be conducted from this general sales office. This commercial side of the business will be under the direction of Mr. Ronald Taylor, who organised and then managed the firm's American business for many years. Mr. F. A. Jones, who has managed the London office for the past thirteen years, will in future act as general sales manager.

Correction.—By a printer's error, which escaped detection, it was not stated in the article on "Two-Colour Studio Portraits," p. 39 of last week's Supplement, that the process there described has been perfected by Mr. J. Newlands Thomson, for Colour Photography, Ltd., of 3, St. James's Street. In remedying this omission we also are requested to point out that it is not correct to say that the business of Messrs. J. A. Thomson, at 22, Brook Street, is being carried on by Mr. Newlands Thomson, the executors of the late Mr. John Thomson having not as yet come to a decision in this matter.

Fireside Portraiture.—Messrs. W. Butcher and Sons, Camera House, Faringdon Avenue, London, E.C.4, have just issued a new booklet, entitled "Portraiture by the Fireside," written by Mr. P. R. Salmon, F.R.P.S., and describing in simple language the many methods of indoor portraiture by artificial light which can be followed during the winter months. The booklet is illustrated by a number of diagrams, showing how to use magnesium ribbon, flash lamps, and flash powder for single portraits, groups, and for special effects, such as silhouettes or firelight studies. There are also hints on developing and retouching the negative. The booklet likewise serves as a descriptive price list of the goods which are required in these branches of photography. Dealers who are alive to the opportunities of business in photographic accessories and materials during the winter months should obtain a supply of these booklets for distribution. They may do so at the cost of 5s. per hundred, inclusive of the printing of their name and address on the covers.

Chinese Prejudices Regarding Colour.—The fact that the Chinese give evidence of decided ideas of their own as to the use of colours in materials, wrappings and poster advertising was recently commented upon by the United States Bureau of Foreign and Domestic Commerce. Such prejudices have been known to cause a Chinese customer to change his patronage merely because of the colouring of packing paper used. Though no definite rule can be applied to all commercial uses of colour, it can be said generally that gold, yellow, red, bright brown, purple, and certain shades of pink are good colours. Gold is a dignified colour, red the colour of good fortune. Imperial yellow is good for rugs, carpets and curtains. White and blue are mourning, and should be avoided as well as green, which is associated with misfortune. The designing of posters and advertising matter should always be handled by agencies in China who are familiar with the tastes and prejudices of the communities involved.

Correspondence.

FINGER PRINT PHOTOGRAPHS.

To the Editors.

Gentlemen,—The interesting article you published last week on the photographic methods of the French police reminds me of a very simple plan of making finger-print "photographs" without a camera.

Mr. Leslie Dunton White, writing in "Dactylography," points out that an easy method of making very good finger prints is by exposing a piece of Seltona paper to daylight until it becomes almost black, impressing the finger on it for three seconds, and then immersing the paper in a solution of potassium permanganate. The finger print then shows up black on a white ground. The paper can be washed in water for a few seconds, and placed in a hypo solution (four ounces to the pint) for half a minute, washed and dried. The method has the advantage of not soiling the fingers; there is no ink to clog up the ridges and whorls of the skin. The result is clear and permanent, and also bears magnification.—Yours truly,

H. Green.

THE ORIGIN OF PICTORIAL BACKGROUNDS.

To the Editors.

Gentlemen,—The reference in the last issue of the "B. J." (page 600) to the late Mr. John Thomson being one of the first to use pictorial backgrounds in studio portraiture is interesting, and the publication of the date would be of even greater interest to those of us who have a taste for photographic history.

I have in my possession two studio portraits (wet plate positives) taken by Thomas C. Lawrence, and dated 1857. These portraits have the original background scraped away, leaving, of course, the bare glass, and are backed up with paper on which is painted a background, a separate hand painted background being made for each portrait. The actual portrait has black paint behind it.

Mr. Lawrence is believed to have been the first photographer in Greenwich, where these two portraits were made, and I understand from his relatives that he used a plain background (afterwards scraping it away and backing it up with a design as described), until he thought of the plan of painting a background and photographing it at the time of making the exposure upon the sitter.

Happily the examples I have are dated in Mr. Lawrence's own writing, but I am unable to ascertain the date of his making pictorial studio backgrounds. It must have been in 1857 or very shortly afterwards, as very few of his combination portrait and background pictures are in existence.—Yours faithfully,

L. Tennant Woods.

EARLY CINEMATOGRAPH PERFORMANCES.

To the Editors.

Gentlemen,—In your correspondence columns of October 5, 1921, under the heading "America's first Movie Show," Mr. Henry Leffmann gives dates, etc., but he does not seem to differentiate between experimental and commercial "shows." I feel obliged to

say that the really "first commercial picture show in America" on a machine using the now standard perforated film was the "Idoloscope," renamed later "Eidoloscope," in Broadway, N.Y. It was built by my father, Mr. Eugene Lauste, for the Lambda Co., of Beekman Buildings, N.Y., in 1894. I was only 14 then, but I well remember the show; in fact, I figured in some actual pictures, taken on the roof of the N.Y. "Police Gazette" building.

I take pleasure in enclosing you a reprint from "The Railway Magazine," December, 1897. You will see on page 5, line 5, that it here mentions the Eidoloscope. Though whether correct or not, it mentions MM. Lumière as having exhibited in France in 1892 "The Cinematograph." Personally, I think it was not shown publicly till 1895, though a Mr. Maisson was working on it in 1894. (*Vide* "Conference sur la Cinematographie," by Ernest Kress, 1912, page 12.)

It simply comes to this: there were many books on cinematography and its origin and history, but none are actually correct, according to the country in which the book is published. So some means are proved that that country is the one where it was first thought of or made possible, whereas, really, it is the outcome of the brains from many inventors working along the same lines unknown to one another, and perfected by the commercial men who had the foresight of its possibilities.—Yours truly, EMILE L. LAUSTE.

70, Wendell Road, Shepherd's Bush, W.12. October 10, 1921.

NEGATIVES AND ENLARGING COSTS.

To the Editors.

Gentlemen,—We are particularly interested in your remarks in "Ex Cathedra" referring to present-day negatives and hydroquinone.

In the course of our business we naturally handle a large quantity of negatives from photographers all over the world, and, judging from the great variation in quality, even in batches of negatives from the same photographer, we think that time and temperature are practically unheeded. Consequently, in order to get even fairly uniform results we have to carry a very large stock of various makes and grades of both bromide and gaslight papers, whereas if time and temperature were considered in development of the negatives we could carry a much smaller stock, could very much increase our output per man, and thereby reduce costs; the reduction of costs would mean a reduction in price to the photographer.

In our copy negative department we use hydroquinone invariably for line work, and also for getting a brilliant reproduced negative from a flat original.

Yours faithfully,
For Raines & Co. (Ealing), Ltd.,
R. H. CHENNELL,
Managing Director

Ealing, W. October 7.

EXHIBITION AND COMMERCIAL PORTRAITURE.

To the Editors.

Gentlemen,—The letter under above heading and signed Godfrey Wilson interests me greatly, it being exactly my own experience during the last twelve years. The present gap between high art portraiture and high-class commercial portraiture is too wide. I certainly would not dare attempt turning out commercially the class of picture I produce for exhibition purposes, and I tremble to think even of the comments of your critic if I were to send up to any exhibition specimens of the ordinary, everyday high-class work turned out by my establishment, and which evidently suits the clients we have.

A few years back I tried an experiment which opened my eyes to the above facts. With every suitable client, when I had taken the number of negatives required for the sitting, I made an extra exposure or two, with the object in view of obtaining a picture something above the ordinary style of commercial photograph, but on submitting a proof of this, which I considered far and away above the other positions, in almost every case the latter were preferred to the picture portrait.

I look forward to more letters on this subject.—Yours faithfully,

GEO. J. HUGHES, F.R.P.S

2, The Mall, Waterford. October 8.

To the Editors.

Gentlemen,—Since my name is mentioned two or three times in the letter signed Godfrey Wilson under the above heading, you will perhaps allow me to add a word or two upon a question which is an old one, and yet seems as far as ever from settlement.

Your correspondent's classification of portrait photography into "exhibition" and "commercial" varieties at once makes a diagnosis of his trouble easy to come at. There are hundreds who are suffering from his complaint, which is art-indigestion. I, too, feel very sick, frequently, at what is offered me to swallow in the name of art, and I think I can help Mr. Wilson if he will try to get my meaning.

He says that the two shows "are not nearly so useful" as the little P.P.A. show. This means that he has little sympathy with the things at the larger shows, but more with the professionals' exhibition. Then he says that between good professional work and "high art" (I accept his bantering term) there is a big gap, across which only men like Crooke and Thomas are able to get. But I take it he thinks it worth while to get across to reach this "high art" which infests the larger shows, not the lesser. It seems to me that he thus cancels out two of the points of his argument and knocks the bottom out of his further complaint that "the average worker fails to do so," *i.e.*, to get across the gap. What is the trouble, then? Is the fault with Thomas and Crooke, or with the average worker who "fails" to follow them across the gap?

I suspect a *soupçon* of the taste of sour grapes. In jumping for these things many an average worker tumbles into the gap. Once there he joins Mr. Wilson in believing professional work more "useful" to him than high art, although to excuse the jump he has to admit that though high it is "excellent" and "not out of place."

The next point is as to the "utter uselessness" of such works as two by Mr. Crowther, about which I waxed rather enthusiastic in a review in this paper. Mr. Wilson instances the case of a very successful man of business who made a practice of showing these useless things outside his studio, but never produced them inside. There are two facts here that want reconciliation: (*a*) This man cannot have thought them useless or he would not have shown them; (*b*) his numerous customers *must* have seen them before they entered. We are not told that his customers were disappointed at getting portraits "produced commercially" instead of the showcase article; but we are told of his prosperity. Where, then, does the uselessness come in?

I think that Mr. Wilson is "bewildered and troubled" because he is mixing up subject-matter in portraiture with feeling and artistic quality. He seems to take the stand that things like "The Showman's Wife," or, to mention another case, Luboshez's clever parody of Orpen's "Chef," are useless because sitters do not wish to be taken as show women and chefs. But sitters are not such fools as that. All they want is evidence of artistic skill in the photographer. I am constantly asked to recommend such. Fanciful and freakish things are, in themselves, no recommendation at all. Mr. Wilson is quite right there; but if they are done well and artistically enough to catch the admiring eye of the passer-by, they are surely a lure. Having lured, it is up to the photographer not to break faith with the lured one by fobbing him off with something "produced commercially." A print in a window is like a hanging sign: virtually it says, "I can sell you this." Too often it is the sitter that is sold.

It seems to me that the professional should shake himself up and get points of view outside of that condition of things which Mr. Wilson says is "of the greatest interest to average studio workers"—the manufacturers' specimens. The manufacturers display these things to show the excellence of their materials, not to attract sitters. The manufacturers look after the professional's technical requirements only too well. The need is all on the artistic side. It is not, I repeat, showmen's wives and theatrical studies, but the eye and the feeling which presents such things in a way that arrests and charms: it is not the sitter, it is the way the sitter is given that professionals must worry about: it is the message that finds conviction in the spectator's experience and catches at the heart; it is the truth and beauty of posing, lighting, modelling and quality. These things matter far more than perfect negatives and immaculate prints. Mr. Wilson says that "given such models" . . . "most studio workers could produce similar results." I ask, then, why

do not they get on with it? The fact is that the actor is not an easy person to treat artistically. He usually leaves too little to the photographer, and Mr. Wilson pays me the compliment of detecting an instance of this defect—a pretty obvious one in a general way

Many years ago I said, what is now a by-word in everyone's mouth, that the amateur is the pioneer of professional photography. Mr. Thomas and Mr. Crowther are scarcely full-fledged professionals, and one could reel off a long list of amateurs whose high art does really mean business.

It is useless to keep on snarling at art. The tradesman has amused himself and his followers a long time with this pastime, doubtless because he rightly despises the freaks and stupidities of which Mr. Wilson complains with justness. But, Heaven help us! These are not art!!—they are stunts!!! harboured by the exhibitions in the hope that they will provide reputation for liberal and up-to-date views as well as a live show.

I am as convinced that the future of photography lies on the lines of true art as I am that the sun will rise to-morrow. But professionals, as a class, cannot see this because, for the most part, they do not know what art is. They think it is "tulle" and "backlighting" and fancy mounting; or they imagine that girls half-dressed in jazz-rags must be art because there is nothing else they can be. One cannot explain, and the case is hopeless except by a long, quiet, reasoned training in appreciative observation and the cultivation of feeling and responsiveness to beauty. When a man knows what is beautiful it is impossible for him to do really ugly things, whatever the subject-matter. A child, a blushing bride, or a weasened old man—either can be beautiful in a picture, but you must know where the beauty lies, and if you are nothing but a technician you never will. The public knows: that is obvious, because the artistic amateur gets on and makes art pay.

F. C. Tilney

To the Editors.

Gentlemen,—I must express my sympathy for Mr. Wilson in his letter of last week. He mentions he has "done" the exhibitions. I rather fancy the exhibitions have "done" him and so bewildered him that I am afraid it will take some time for his recovery. However, I sincerely hope he will rally in time to send of his best to our next exhibition.

I fancy I am in a position to speak, having been the only professional this year who has seen every picture sent to London for our three great photographic exhibitions—the Congress P.P.A. Exhibition, the Royal and the London Salon of Photography—and I contend that Mr. Wilson makes statements in his letter which are entirely misleading. He has expressed himself in bewildered language.

The standard of works submitted this year, on the whole, was higher than I have ever seen. Of course, it is foolish to think that every picture selected is a masterpiece. This is impossible, but if one feels a work is uninteresting why bother about it? Pass it by and dwell in peace on the beauty of the pictures you do appreciate. Mr. Wilson is very unfair in his judgment of the shows, inasmuch as there are pictures on those walls that are real masterpieces of photography and art, and I contend any client would be very proud to receive portraits as distinctive as many in this year's shows.

With regard to the Miss Margrethe Mather portrait of a lady, it is a fine piece of work. I care not what anyone says, it is a masterpiece of photography and has a big lesson to teach us all! Only a clever mind could have dared such a big bold stroke. This is where the ordinary professional man is lacking. Firstly, he is not educated to the point of seeing; he is asleep in the slumber of conventional thinking, and all the time he thinks in plain ordinary thoughts, and this is just one reason why photography is stale and photographers all classed as a dull, uninteresting set

I do not think Mr. Wilson realises it is just such pictures as these that will help to keep the photographer awake and induce the public to seek the live man; it stimulates talk and creates business; not necessarily the photographing of backs.

Again, Mr. Wilson is misinformed when he makes the broad statement regarding commercial portraiture. He has much to learn on this point. All I can say is, I am glad the world is large enough and has enough people in it to satisfy Mr. Godfrey Wilson and several others whose works are hung on the walls of these exhibitions, although Mr. Wilson has avoided mentioning their names in his letter of bewildered depression.

Mr. Wilson will be glad to learn that Mr. Pirie MacDonald expressed to me his appreciation of the wonderful advance British portraiture is making, judging entirely from these exhibitions.—Yours very sincerely, Marcus Adams.

43, Dover Street, Piccadilly, W.1.

ILLUMINANTS IN ENLARGING: FILMS v. PLATES.

To the Editors.

Gentlemen,—Absence on holiday is my excuse for these somewhat belated remarks. It is unfortunate that your article of September 30 does not draw attention to the fact that some anastigmats do not work to focus when used on an enlarger with electric light, either arc or incandescent. Before buying the projection lens it should be ascertained if it suffers from this disability, which may be shown by instruments that give exquisite definition when used on a camera in the ordinary way.

In the films v. plates controversy, it should not be lost sight of that the grain of films is much coarser than that of plates having considerably greater rapidity. The enclosed test pieces show that the film grain is unpleasantly apparent at two diameters (quarter to whole-plate), while that of a 400 H. & D. plate is practically invisible.—Yours faithfully, Old Hand.

Canonbury, N.1. October 5.

PLATES v. FILM.

To the Editors.

Gentlemen,—That such an unusual step as that taken by us in discontinuing the manufacture of glass plates should have caused a very considerable amount of comment in the photographic Press was to be expected. We have not, therefore, been surprised at the number of letters "to the Editor."

To answer the minor points brought out by your correspondents, although we believe them to be readily answerable, would be to continue a useless controversy.

There is just one answer: the quality of Portrait Film is such that its universal use is inevitable. We have been making film for more than thirty years. For more than twenty-five years we have felt profoundly certain that the day would come when film would displace plates for professional use. Eight years ago Eastman Professional Film was placed upon the market with modest claims. Since then it has made its own place, both in the finest studios and in studios where the greatest volume of work is turned out, simply because it makes better negatives than plates ever made or can make.

There is an inherent advantage in the use of a thin film base over the use of glass: the prevention of that arch enemy of quality—halation. Film does not merely give somewhat better negatives with the usual lightings. It unfetters the photographer, enables him to do the bold and unusual things in lightings, and, at the same time, retain quality. It has a plasticity that no mere plate has had or ever can have.

Some of your correspondents have expressed the opinion that Portrait Film is not fast enough for their particular requirements. We have realised for some time that, especially in the winter months, a faster emulsion would be a help to a large number of professional photographers. With this in view, we have for several months past been experimenting, and are now in a position to announce that, within the next few weeks, we shall put upon the market a very much faster grade of Eastman Portrait Film called "Super speed." This "Super-speed" Film will be approximately twice the speed of our regular Eastman Portrait Film.—We are, yours faithfully,

Kodak, Ltd.,
F. C. Mattison, Managing Director.

October 11.

Answers to Correspondents.

In accordance with our present practice a relatively small space is allotted in each issue to replies to correspondents.

We will answer by post if stamped and addressed envelope is enclosed for reply, 5-cent International Coupon, from readers abroad.

Queries to be answered in the Friday's "Journal" must reach us not later than Tuesday (posted Monday), and should be addressed to the Editors.

R. L.—So far as we know, no such paper is manufactured, and up to the present it has not been found possible to make a printing paper which will make colour prints from colour negatives.

R. K.—We cannot see any advantage in the proposed alteration. If you had a northern aspect the steeper pitch would help to keep the sun out, but in your case it will avail nothing. Also from your plan, which is not very clear, it would appear that you would sacrifice something in the height of the side light, which is low enough now

E. L.—(1) You can have the lens tubes slit and Waterhouse stops fitted in the case of most anastigmats, although not all. If the work is properly done a thick elastic band round the tube should be sufficient to prevent entrance of light into the mounting. (2) An elastic band could be used if no loose diaphragm was inserted. (3) There is no means of readily calculating the place for the insertion of the stop. The makers could give this information, and in fact it would be best to allow them to fit the diaphragm.

J. S.—(1) The distance required between the sitter and the plate when taking a full length cabinet with a 9½-inch lens is almost exactly 12 feet, supposing the sitter to be 68 inches high. (2) "Cabinet head" is a little vague, but if the sitter's head is reproduced one-third scale, that is, 15 inches to 5 inches, the distance required between the sitter and the plate with a 14-inch lens is just over 7 feet. We cannot attempt to reconcile the figures given in the "Almanac" table with those which you quote from a lens maker. If you like to send the lens maker's booklet we could perhaps do so.

E. J.—We should think that, on the whole, incandescent gas would be your best choice. About a dozen Howellite inverted burners would allow you to give quite short exposures with such a plate as the Iso Record. The acetylene would probably be a little quicker, but you would get nothing like 8,000 c.p. out of twenty burners; 1,000 c.p. would be nearer the mark. You have also to consider the fumes from the light while burning; with twenty burners in a small studio the operator would probably get a bad headache, even if the sitter did not. If you had not very many sitters a flashlight on the Tress principle in which incandescent gas is used to focus by and a gas ignited flash for the exposure is worth considering.

D. C.—You will find your first three questions answered more fully than is possible by letter in the little book, "The Portrait Studio," obtainable from our publishers, price 1s. 3d. post free. Referring to your more particular inquiries, we do not think that you could do better than to get the *f*/3.5 Cooke lens. This will cover well for groups, and will also do for outdoor work, and has besides a convenient soft focus adjustment for portraiture. At the same time we would point out that 12 inches is rather a short focal length for large cabinet heads, and as you contemplate having a large studio a 16-inch or 18-inch lens would be a better choice. You would, however, require a 12-inch lens, or even one of rather shorter focus, for full lengths and groups. It should not be difficult to convert an army hut into a good studio. You would not, in any case, require the full 60 feet in length, but by fitting partitions you could arrange for work and reception rooms.

G. M.—Messrs. W. Butcher and Sons, Ltd., Camera House, Farringdon Avenue, London, E.C.4, and Messrs. Houghtons, Ltd., 88-89, High Holborn, London, W.C.1, supply cinema cameras of simple construction. The best journal for you is the "Kinematograph Weekly," published by Messrs. Odhams, Ltd., Long Acre, London, W.C.2, price 3d. You can get second-hand machines from the City Sale and Exchange, 81, Aldersgate Street, London, E.C.1, and other dealers. The mechanism of a camera would require to be radically altered in order to make it suitable for taking single exposures one after the other, and so that the portrait could be focussed in each instance. For this it would probably be necessary to use a lens of, say, 7 or 8 inches focal length. Such a lens can be adapted to many cinema cameras. For satisfactory work postcard size is about as large as the little cinema negatives can be enlarged. We do not quite understand what you mean by using cinema film for bromide contact work. Certainly transparencies can be very readily made on the cinema positive film

SALE OF NEGATIVES.—I recently purchased the negatives (view and portrait) of a firm of photographers when they went into voluntary liquidation. I purchased simply the negatives, and not the right to use their name. The firm I am now with are open to purchase a quantity of the negatives. About the view negatives I presume there is no difficulty. But can I sell outright to my firm negatives taken in the ordinary way of business of ordinary sitters that may be useful for show-card advertisement purposes?—N. E.

The copyright in the portrait negatives, or in any others which were made by the original firm in execution of an order from somebody or other, is the property of that somebody or other, and any use of the negatives for the purpose of making show-cards, etc., will be an infringement of the copyright. We have no doubt you are entitled to sell the negatives (it is rather an obscure point on which there have been no cases in the Courts), but certainly the purchaser will have no right to print from them, and you are not competent to grant him such right.

D. N.—It would be easier to answer your query if you had enclosed a sketch of the stands on which your lamps are mounted, as upon the form of these the nature of the reflector must largely depend. If the stands are those supplied by the General Electric Company you cannot do better than to adopt the company's hemispherical reflector. The diffusing arrangement supplied with this is not quite effective, and a great improvement can be made by fitting a conical wire shade covered with thin nainsook over the entire front, as shown in sketch we send. If you find these reflectors too expensive, a D-shaped tin reflector with a nainsook front will answer as well, but will not be so sightly. To get even lighting of full lengths the lamps should be 8 feet from the floor. This will give too much light to the head, so to avoid this you should use a semi-transparent head screen to cast a slight shadow on the upper part of the figure, and thus allow you to expose fully for the legs and feet. With groups this screen will not be necessary, as the light will have about the same distance to travel for the heads of the back row (standing) and those of the front row sitting. Reflectors are used as with daylight.

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 3207. Vol. LXVIII. FRIDAY, OCTOBER 21, 1921. Price Fourpence.

Contents.

SUMMARY.

It is fifty years since the foundation of the modern gelatine dry-plate emulsion was laid by the publication in the "British Journal" of the paper by Dr. R. L. Maddox. (P. 321.)

In a leading article we describe a method of producing portrait negatives of semi-soft focus which has just been made known in France, and is attracting considerable interest there. Two plates are exposed, one behind the other, and are differently developed. (P. 622.)

In a contributed article Thremit deals with some of the technical and commercial points connected with at-home portraiture. (P. 626.)

The opportunities for the arrangement of portraits within a horizontal oblong space are perhaps not sufficiently realised by portrait photographers. (P. 622.)

Further correspondence on the commercial advantage of artistic portraiture will be found on page 634.

Messrs. O. F. Bloch, F.I.C., and F. F. Renwick, F.I.C., discuss the mechanism of desensitising with potassium iodide according to Freund's process in reference to the recent paper on this subject by Mr. Thomas Bolas. (P. 627.)

A Canadian contributor, Mr. Charles Macnamara, in a realistic description of outdoor conditions during the winter in northern America, emphasises the disabilities of certain items of photographic equipment. (P. 623.)

Mr. A. Lockett has worked out a rule for calculating the nodal space of a lens, that is, the interval which requires to be taken into account in exact calculations of the distance from object to image, or *vice versa*, in copying or enlarging. (P. 624.)

An ingenious method of electrically indicating the setting of a copying camera in focus for any particular scale of reproduction is described in an article on a new equipment of the U.S. Geological Survey. (P. 628.)

Professor Carroll B. Neblette, in a paper in "American Photography" on the fixing bath, prescribes a rule for the number of plates which can with safety be fixed in a given quantity of hardening-fixing bath. (P. 626.)

Dr. B. T. J. Glover discusses the conditions requiring to be fulfilled in the systematic use of a single printing paper for printing or enlarging from negatives of different subjects. (P. 634.)

Stereoscopic cinematograph projection and a gas-heated dry mounting fixing iron are among the patents of the week. (P. 629.)

The Scottish Salon will be held next year at Hamilton, from February 11 to 25. (P. 630.)

A precaution in the use of a roller-blind shutter out of doors is the subject of a paragraph on page 621.

EX CATHEDRA.

Roller-Blind Shutters. Those photographers who use the popular roller-blind shutter should be on their guard when working out of doors, when a breeze is blowing, against the possibility of spoiled negatives. We refer to the probability of the wind catching the cord of the shutter while the latter is open for the exposure of the plate, and turning it round some portion of the camera front, so that a proper closing of the blind is prevented. Some time ago we had this happen when using a large field camera, the shutter cord getting caught round one of the milled heads operating the swing front, with the result the plate was spoiled. It is a good plan to guide the passage of the cord with the palm of the hand while an exposure is being made, especially if of "bulb" or "time." This, of course, does not apply so much to the before-lens shutter, since in all probability it will be far enough away from the camera front to ensure that its progress during the exposure will not in any way be impeded.

* * *

Fifty Years of Gelatine Emulsion. It was in the autumn of 1871, the year of the Tichborne trial, that Dr. R. L. Maddox published, in the "British Journal of Photography," the paper describing the preparation of a gelatine emulsion which, within the subsequent ten years, had begun to revolutionize the practice of photography throughout the world. Yet the publication attracted scarcely any notice at the time. The energetic Thomas Sutton, in the following issue of the "B.J.," prophesied the approaching substitution of gelatine for collodion as the vehicle of sensitive silver salts, but in his review of the year's progress in the succeeding "Almanac," Traill Taylor did not even mention Dr. Maddox's contribution. And when the principle of process described by Maddox is studied, it is perhaps not surprising that photographers of that day should have failed in discerning any great possibilities of gelatine displacing the established collodion process. In point of fact nothing more was heard of gelatine emulsions for nearly two years; the next sign of interest in it was an advertisement in the "B.J." of July 25, 1873, by Mr. J. Burgess, offering for sale what was afterwards discovered to be a gelatine emulsion. That publication, however, did much to promote subsequent experiment with, as the names of Kennett, King, Johnston, Burnett, Watton, and others are associated. The succeeding five or six years were characterised by great activity in the new field, and those who may wish to trace the evolution of the gelatine emulsion during this period cannot have a better means of doing so than the article by W. B. Bolton in the "B. J. Almanac" of 1880. It is notable in all this how closely experimenters clung to traditions of the collodion emulsion process, and how, by slow degrees, the technical conditions which applied particularly to the latter were discarded.

Wide-Angle Lenses. The equipment of most photographers includes a wide-angle lens, though many workers do not seem to realise that these instruments may be of great value, apart from the particular purpose for which they are primarily designed. When copying has to be done upon a fairly large scale, and the camera extension at the photographer's disposal is not enough to permit the required size of picture with the lenses ordinarily employed for this work, the short-focus wide-angle lens may be pressed into service with excellent results. In this branch of work the violent perspective too often in evidence in pictures taken with short-focus lenses is not generally noticeable. Again, most wide-angle lenses are separable; their components, in common with other lenses of the doublet type, are usually about twice the focal length of the complete lens, and with smaller stops give quite good definition. This fact may sometimes be of advantage in giving an additional choice of focal length not possessed by any complete lens at the photographer's command.

* * *

Vertical or Horizontal. Many photographers are at times in doubt as to whether a particular picture should be taken the vertical or the horizontal way of the plate. In effect, the vertical picture conveys an impression of strength and dignity, while the other rather of breadth, space, and distance. This is, of course, mainly applicable to landscape or view work, though in some ways the idea may be applied to portraiture. It is sometimes possible to strike a new and distinctive note, by composing a portrait photograph in the horizontal, instead of the usual vertical way of the plate, particularly when the sitter can be posed so that the lines run to length and breadth, rather than height. We were recently shown a very charming garden portrait of a lady reclining in a deck chair, and this particular portrait required a certain originality of treatment, simply because the lines of its composition took a form different from the usual vertical. Sometimes the choice of a horizontal position for the plate is a decided mistake. Some time ago we noticed one of the ordinary "bride and bridegroom" pictures, taken upon a lawn. The plate had been exposed in the horizontal position, with the result that far more of the surroundings were included than there was any need for. These pictures should seldom be attempted other than with the plate in the vertical position.

* * *

Hardening Roll Films. Those who use roll films after a long experience of dry plates are inclined to treat their negative medium rather too harshly when developing and fixing. It must be kept in mind that film in any form is decidedly more tender than glass negatives, and will stand very little ill usage without softening or frilling, in which case it is very prone to scratches and other forms of mechanical damage. This is especially the case in hot weather, when it is practically impossible to keep solutions at a temperature low enough to ensure immunity from trouble without the use of ice. It is always a good plan to use a hardening bath, such as formaline or alum, preferably the former, between development and fixing; or, if this is not done, an acid fixing bath, which will also harden the film, should be employed. One caution should be given when using an alum bath between developing and fixing. The alum bath must not be too strong, or the film may be given a dirty appearance difficult to remove; also, the film should be well washed, after being taken from the developer, before being put into the alum bath, or the alkali remaining in the emulsion may contaminate the alum bath, with the same result. In this respect chrome alum is better than ordinary alum. Another cause of scratches may often be traced to the rough ends of the film travelling over the strip when in the washing water. These should always be cut off, or they may be attached to a cork with a drawing pin, the film being suspended in a loop in the washing water. If this is done, scratches will not occur, even though the gelatine coating is in a soft state.

A TWO-NEGATIVE SYSTEM FOR SOFT-FOCUS PORTRAITS.

A process of more than ordinary interest to portrait photographers is described and illustrated in the current issue (No. 44, October 15) of our contemporary, "La Revue Française de Photographie." It is a method of introducing a certain amount of soft definition into a portrait and at the same time of modifying to a very considerable extent the scale of tones and even such features as the texture of the background. The method has long been employed by a painter and sculptor, M. E. Artigue, son of the M. Artigue who formerly made a direct pigment paper with which the early triumphs of Demachy, Puyo and other French pictorialists were obtained more than twenty years ago, but which is no longer manufactured. M. Artigue has disclosed his method to a contributor to our contemporary, M. W. Quatreboeufs, who, in an introduction, gives his reasons for regarding it as the realisation of an ideal technical method hitherto sought in vain among soft-focus lenses and other devices. According to M. Quatreboeufs, whose curious name is, perhaps, a nom-de-plume, one must have in a portrait—or in a landscape, for that matter—acute definition, or "sécheresse," as the French call it. But having got that, it must, so to speak, be enclosed or, as our French writer puts it, be given an "enveloppe." From this standpoint the result obtained with a lens which yields an image more or less wanting in definition is unsatisfying, since it lacks the precision which is regarded as the first essential; and the customary retouching, in the view of the writer, is worse still. On the other hand, M. Artigue's method is found to yield results which exhibit this union of definition and "medium." We hear that his work in portraiture has received the cordial admiration of French art critics.

In practice, M. Artigue's method is very simple. He exposes two plates in the camera, one behind the other, and with the emulsions' films of both directed towards the lens. The two sensitive surfaces are therefore separated by the thickness of the front plate. It is necessary to give an exposure about half as much again as for a normal negative, in order to obtain sufficient light-action on the rear plate. The front plate is very lightly and superficially developed; its function is to yield detail and sharp definition. The rear and somewhat under-exposed plate is, however, developed thoroughly in order to obtain a vigorous scale of tones. The two negatives, when superimposed in register, should together form one of about the normal density. For use, they are thus bound together in register with gummed strips in the same relative positions as when exposed in the camera. From the composite negatives prints are made in the ordinary way, that is to say, with the paper in contact with the film of the sharp negative of the pair.

Nothing is said in the article in our contemporary respecting the working aperture of lens which is suitable to this process, but presumably a large aperture, such as $f/4$ or $f/6$, is intended to be employed; otherwise the degree of softness of definition produced on the rear plate will be insignificant. Moreover, in view of the longer

time of exposure which requires to be given, a large aperture may be assumed to be a necessity under the ordinary conditions of portraiture. Two half-tone reproductions of photographs obtained by the process are certainly a recommendation of it. One of them, a half-length portrait of a woman, has an indefinable mixture of softness and sharpness, and also exhibits what apparently is the result of considerable after-work upon the rear negative. It seems that M. Artigue does not tamper in any way with the thin sharp negative obtained on the front plate, but as regards that made on the rear plate permits himself to carry out any description of work, in the way of retouching or local reduction or intensification, which, it is judged, will fit in with his artistic aims. Apparently, in the portrait which we have just referred to, a good deal has been done to the rear negative by way of introducing a species of soft hatching of the background. Evidently, work of this description may be done somewhat coarsely, the separation of the rear negative from the printing paper serving to soften such handwork in the final print. The other specimen, having as its subject the head of an old man, shows a print from each component negative alongside one from the two negatives combined. It is evident that a large-aperture lens has been used, the negative on the rear plate being quite out of focus. Apart from the intermingling of a certain degree of soft focus in the prints, the method would seem to provide the means for securing a rendering of detail throughout a wide range of light intensities in the subject, and possibly in this respect has as much to recommend it as in its introduction of soft definition. The possibilities of two successive emulsion films for the rendering of a long scale of tones have in the past been proved in the case of double-coated plates, such as those formerly manufactured by Mr. Sandell. Here the result is somewhat similar, but with the added facility of producing localised effects by treatment of the rear negative.

BELOW-ZERO PHOTOGRAPHY.

If I say that where I live in the Ottawa Valley we never have any excessively cold weather I may seem to be echoing that patriotic resident of the Yukon who deprecated the reports of extremely low temperatures alleged to occur in his country. "These stories," he said, "are all greatly exaggerated. I have lived there for many years, and the lowest I ever saw the thermometer was only 65 deg. below zero!" After that, our unassuming minimum in Eastern Ontario of 35 deg. below is scarcely worth mentioning. And even this moderate—that is to say, *relatively* moderate—temperature is seldom suffered by the photographer in the pursuit of his art in the open. For the lowest record invariably occurs just before sunrise, and the temperature goes up steadily with the sun, so that by the time the light is favourable for photography the thermometer rarely stands lower than 20 deg. below zero.

I do not think there can be any finer weather in the world to be out in than 20 below zero on a bright, still morning, when the well-packed snow affords good snowshoeing. The keen, dry air is so stimulating that one can travel all day without fatigue; and, strange to say, in the cold the camera loses its well-known property of doubling its weight every hour it is carried. If there has been a fall of snow in the night, the surface glitters under the early sun in millions on millions of diamond sparks. The dry snow creaks under the snowshoes, but the woods are very silent. Only a few birds stay with us through the winter, and none of them move around much in very cold weather. But now and again a sharp crack rings through the forest like a pistol-shot. Water lodged in some crevice of a tree has been expanded into ice by the intense frost, and has suddenly riven open the wood. Everything is rigid with the cold. The pine-needles stand out in tufts as stiff as wire, and as one pushes through low-hanging branches the twigs break off like glass.

As long as I keep moving I am quite warm and comfortable, but when I come to set up my camera I begin to realise that it is really a cold day. To manipulate small screws and make fine adjustments with thick buckskin mitts on is an impossibility. It has to be done with bare hands. In less than two minutes my hands are numb and aching with the cold, and the mitts must be put on again for a while until feeling and circulation come back into my fingers. There may be trouble getting a firm footing for the tripod in the deep snow, but by tramping around heavily on snowshoes a fairly solid bottom is obtained. An utter abomination when working in the snow is a flimsy tripod. One winter morning I proudly started out with a beautifully-made little wooden tripod of several ingenious folding and sliding sections. On firm ground it was, perhaps, strong enough for my camera, but in the uncertain foundation of the snow one leg sank deeper than the others, it toppled over, and the weight of the camera pulled it down sideways. When I picked it up I counted eight places where it was split or broken. The loose tripod top and the three separate legs that have to be carried like a bundle of sticks are also anathema in the cold. Indeed, any apparatus that demands avoidable handling is to be shunned in zero weather.

When focussing with my head under the cloth, if I happen to breathe on the ground glass, my breath freezes on it in a coat of rime that has to be scraped off before I can proceed. Late one cold afternoon I was preparing to make an exposure, and as I bent down to set the diaphragm I inadvertently breathed on the lens. Instantly it was coated over with ice. Without thinking, I breathed on it again, with the foolish idea of melting the coating. But the effect was merely another layer of ice over the first one, and as there was no possibility of getting the lens thawed out before the light was gone, I simply had to pack up and make for home.

Low temperatures have no bad effect, I believe, on the speed of plates, indeed, all sensitive materials keep excellently in our dry, cold winter weather. But Jack Frost plays what the photographer must consider very stupid tricks with apparatus. Many wooden cameras of European manufacture warp and split here over winter. Strong-springed shutters of the "Compound" type continue to work quite satisfactorily at the lowest temperatures I have ever experienced, but some of the lighter patterns of diaphragm shutters are slowed up or stopped altogether by the cold, and the focal plane shutter also gives in when the thermometer sinks to anywhere near zero. Consequently, the reflex camera is practically useless here in winter. Our ruffed grouse has a habit of burying itself in the snow as a protection from the cold, and I have long wanted to photograph the bird bursting out on the wing from its burrow in the drift. My sector shutter set at 1/50 second on the scale goodness knows what the speed really is—only gave me a negative with a streak of grouse 6 ft. long. So I tried a reflex camera that I had used with perfect satisfaction in the summer. But after the first half-hour in the open the inexorable cold gripped its inwards, and when I reached the grouse resort the shutter was so stiff with the frost that even at the highest spring tension it refused to work. And so the grouse still leaps from its snow burrow unphotographed by me to this day.

If you demand mist in your landscapes, you won't go out

to photograph them at 20 below zero. In such weather you will find no soft, hazy vistas; everything is clear-cut and keen. The naked branches of the distant hardwoods are wiry sharp, and you can see the pine trees fringing the skyline of the blue and silver hills thirty miles away. There is nothing vague or illusive about the scene. A Canadian winter day is a hard, cold fact.

For the nature photographer the season affords many interesting subjects. For instance, there is a new kind of botany to be studied in the numerous plants that stand above the snow, leafless and flowerless now, but frequently offering fine compositions against the pure white background. An even more interesting series can be made from wild animal tracks in the snow. Only a few of our animals hibernate, and although the soundless woods and fields seem bare of life, the snow betrays the presence of many creatures large and small, and relentlessly publishes all they have been doing. The moose, the wolf, the lynx, the otter and other rare fur-bearers must be sought farther north; but even in the settled country where I live tracks of the red deer, beaver, porcupine, fox, mink, hare, marmot, weasel, red squirrel and sundry mice and shrews are more or less common.

With a modicum of woodcraft, the snow-gazette is not hard to read. It gives news of many intimate happenings in animal life, of friendly visits and social gatherings in the moonlight, of courtships, hunting expeditions and intrepid travels; and, alas! all too often, of battle, murder, and sudden death.

In photographing the tracks the best results are obtained with panchromatic plates and colour screens, a red screen being sometimes useful to give contrast in the snow on a cloudy day. And a tilting top for the tripod is more than a mere convenience—it is a practical necessity.

CHARLES MACNAMARA.

FINDING THE NODAL SPACE OF A LENS.

PRACTICALLY all popular formulæ dealing with the distances necessary for enlarging or reducing stop short after stating the conjugate foci for an image in a given ratio, with a lens of a given focus. It is left to the uninitiated worker himself to discover, often with bewilderment and chagrin, that the sum of the two conjugates is seldom the precise total distance requisite for a desired size of image.

As anyone acquainted with optical theory will be aware, the explanation is that the two conjugate distances should not usually be measured from one identical point, but from separate points, known as the first and second nodes, or the nodes of admission and emission. The nodes may be defined as those points where converging rays from the object, or diverging rays to the image, would cut the lens axis, if they were to continue through the glass, or be produced back in a straight line, without refraction or bending. According to the optical design of the lens, the nodes may either be inside it or outside, and sometimes the second node is in front of the first instead of behind, in which case the nodes are said to be crossed. They rarely coincide.

The foregoing will make it evident that the correct total distance between negative and enlargement, or original and copy, will be the sum of the two conjugates plus the distance between the two nodes, called the nodal space; while if the nodes are crossed the nodal space must be subtracted from the sum of the conjugates instead of added.

But how is the nodal space to be ascertained? If the photographer knows the precise focal length of his lens that is an easy matter. He has only to focus an enlargement or a copy carefully to an exact ratio, to measure the distance from negative to image, or from original to ground glass, and to find the difference between that measured distance and the sum of the conjugates required for the given ratio with a lens of the given focus. Thus, suppose the lens is known to be of 8 in. focus, the ratio of enlargement or reduction is 2 diameters, and the measured distance between object and image is 35¼ ins. Looking up the conjugates for a ratio of 2, in a table of distances, we find them to be 24 ins. and 12 ins., or 36 ins. altogether, and subtracting 35¼ from 36, the nodal space is found to be ¾ in., the nodes in this case being obviously crossed.

Providing all the measurements have been very carefully done, we can now always enlarge to any desired size with that lens, or reduce, by simply calculating or looking up the sum of the conjugates, subtracting ¾ in., measuring the resulting distance between negative and easel, or object and plate, and moving the lens alone until sharp focus is obtained with the largest stop.

But when, as most frequently happens, the worker does not know the exact focal length of the lens, or disbelieves its supposed focus, matters are more involved. As far as the writer is aware, no formulæ have yet been published dealing with such circumstances, except those calling for the use of an expensive optical bench and a nodal slide or turntable. The following formula, the result of much patient calculation and experiment, may therefore be of service to many. In spite of its somewhat forbidding appearance, it is really quite simple, while the whole of the measurements and reckoning can be carried out in a few minutes, requiring nothing but the every-day appliances of the studio.

Two different ratios and total distances have to be measured. Much the easiest way of doing this, in the case of an enlarger, is to use as the negative a plain glass having on it a black line exactly 1 in. long. Then the measurement of the line in the enlarged image will itself be the ratio. Thus, if the image measures 2 ins., the ratio is 2, and so on.

Having first focussed one image sharply with the largest stop, measure the ratio, and also the total distance from negative to image. Then focus another image sharply a diameter or two larger, again measuring the ratio and the total distance.

Let D_1 = first total distance, D_2 = second total distance. R_1 = first ratio, and R_2 = second ratio. Then,

$$D_2 - \frac{(D_2 - D_1) \times \left(2 + R_2 + \frac{1}{R_2}\right)}{(R_2 - R_1) - \left(\frac{1}{R_1} - \frac{1}{R_2}\right)} = \text{the nodal space.}$$

For example, suppose the two ratios are 3 and 5, while the two distances are 54 1/3 ins. and 73 ins. Then,

$$73 - \frac{(73 - 54\ 1/3) \times (2 + 5 + 1/5)}{(5 - 3) - (1/3 - 1/5)} =$$

$$73 - \frac{18\ 2/3 \times 7\ 1/5)}{2 - 2/15} =$$

$$73 - (2016/15 \div 28/15) =$$

$$73 - 2016/28 =$$

$$73 - 72, = 1 \text{ in., the nodal space.}$$

Since 73 ins. is the actual total distance with a ratio of 5, it is evident that 72 ins. is the sum of the conjugates for that ratio. Knowing this, it is easy to find the true focal length of the lens, which is always equal to the sum of the conjugates divided by $\left(2 + R + \frac{1}{R}\right)$. Thus, $72 \div (2 + 5 + 1/5) =$ $72 \div 7\ 1/5, = 10$ ins., the focal length.

Having once ascertained the nodal space and the focal length of his lens, the worker will in future be able to make enlargements or reductions to any desired ratio without further trouble, in a manner that is far quicker and more

satisfactory than the usual rough-and-ready series of shiftings and readjustments. Suppose, for instance, it is wished to enlarge to exactly 2½ diameters. Then, $10 \times (2 + 2\frac{1}{2} + 1/2\frac{1}{2}) = 10 \times 4\ 9/10, = 49$ ins. Adding 1 in. for the nodal space, the required total distance is 50 ins., when it is only necessary to place the easel 50 ins. away from the negative, and to focus sharply at full aperture by moving the lens alone.

Should the calculated amount obtained by the nodal space formula prove to be greater than that from which it is to be subtracted, the remainder is a minus quantity, through the nodes being crossed. Thus, suppose the calculation were to end as 65 – 65 8/10, the result would be – 8/10 in., indicating that 8/10 in. (the nodal space) is always to be deducted from the sum of the conjugates instead of added, when in future measuring the total distance for an enlargement or reduction.

In the case of a copying camera, when making the preliminary tests to ascertain the nodal space, the best way is to fix up a 2-ft. rule horizontally in a good light, and to mark two vertical lines on the focussing screen exactly 2 ins. apart. The position and focus of the camera are then adjusted, using the full aperture of the lens, until a certain number of inches in the image exactly fill the space between the lines, taking care to keep the camera back parallel to, and square with, the rule. The number of inches included, divided by 2, will obviously give the ratio; for instance, if the number is 8, the ratio is 4. The distance from rule to ground glass should then be measured carefully, and the operation repeated for the second ratio, this time getting a larger number of inches between the lines.

A. Lockett.

THE FIXING BATH.

(A Paper in "American Photography")

After the plate has been developed it is still sensitive to the action of actinic light because of the undeveloped bromide of silver. When development is complete there is still a layer of emulsion next to the glass and coming to the surface in the deepest shadows which neither the light nor the developer have acted upon. It is the function of the fixing bath to remove the unaltered silver salt and render the negative permanent by leaving only metallic silver embedded in gelatine.

There are but few substances which will readily dissolve silver bromide. Sodium thiosulphate, which we commonly term "hypo," is used to the practical exclusion of all others because of its efficiency and cheapness. Hypo has the formula $Na_2S_2O_3.5H_2O$. It is prepared by the treatment of calcium thiosulphate with sodium sulphate. The salt is easily recrystallised and the commercial samples are sufficiently pure for photographic purposes. It should be free from acid and the crystals should not possess a yellow tinge. It is soluble in one to two parts of cold water and in one part of boiling water.

Hypo dissolves silver bromide by uniting with it to form soluble silver thiosulphate.

$$AgBr + Na_2S_2O_3 = AgNaS_2O_3 + NaBr.$$

If the bath is too weak, due either to improper composition or to over-use, instead of the soluble salt $AgNaS_2O_3$ there is formed an insoluble double salt having the formula $Ag_2Na_2(S_2O_3)_2.2H_2O$. The incomplete elimination of this insoluble salt is the chief cause of fading and staining of prints and negatives.

We may classify the various fixing baths into three types—plain hypo, the acid fixing bath, and the acid fixing and hardening bath. The first is still in use in Europe but is gradually passing there with the introduction of D.O.P. In this country it has completely gone out of use. A certain amount of developer is carried over on the surface of each print or negative transferred to the fixing bath. Since all developing agents are easily oxidised, particularly when in very dilute solutions, even this small amount will soon oxidise and colour the bath, causing stained negatives. In the case of prints the developer is absorbed by the paper and consequently there is greater danger from stain than is the case with glass negatives, so that for prints some addition to the bath is absolutely necessary to prevent oxidation.

The sulphites have the property of preventing the oxidation of the developing agents and it is for this reason they are added to our developers. The preservative action of sulphite is greater if the bath is kept in a slightly acid state. If an acid alone is added to hypo, the hypo will be decomposed and sulphur will be precipitated. This is owing to the fact that acids convert sodium thiosulphate into thiosulphuric acid, which decomposes into sulphurous acid and sulphur. The action is reversible, since we can prepare hypo by boiling together sulphur and sodium sulphite. Consequently the acid and sulphite in the fixing bath, in a sense, work in opposition to each other and we can prevent decomposition of the hypo by the acid, providing there is the proper amount of sulphite added. This is accomplished in two ways: by the use of acetic acid and sodium sulphite, or by sodium bisulphite which has the composition $NaHSO_3$ and is equal to a combination of sulphite and acid.

The following is a suitable formula, using sulphite of soda:—

Sodium thiosulphate ("hypo")	16 oz.
Sodium bisulphite	3 oz.
Water	64 oz.

In large establishments the bisulphite should be made up as a stock solution and added to the hypo, one ounce of a 50 per-cent. solution to each twenty ounces of plain fixing bath.

Sodium bisulphite lye is often used in making acid fixing baths. It is obtainable commercially, but is easily made by adding one-half ounce of sulphuric acid to seven ounces of water and then adding, after cooling, four ounces of sodium sulphite. This quality may be used in the above formula.

Potassium metabisulphite may be used in place of sodium bisulphite. It does not decompose quite so readily but has the disadvantage of costing more and practically the bisulphite is to be preferred.

The third type of fixing bath, the acid hardening bath, is an acid bath to which an alum has been added to harden the gelatine. It contains the following ingredients:—

a. An acid to stop development—usually acetic.

b. A hardening agent, such as alum or formaline.

c. A preservative—usually sodium bisulphite.

There is another, less common bath, in which sodium bisulphite replaces acetic acid and sodium sulphite.

In mixing the hardener it is best to use two separate solutions. Dissolve the alum and sulphite each in one-half the total amount of water. Then add the acid to the sulphite solution and finally mix the two solutions.

If the bath turns milky upon standing it is due to:—

1. Too much acid or the use of too strong acid (most formulas call for 28 per cent. acetic acid).

2. Too little sulphite, bad sulphite, or high temperature of solution.

If the milkiness disappears on standing it is due to the use of an insufficient amount of acid or not enough hardener in the bath to overcome the developer carried over by large amounts of prints.

If the bath does not harden the emulsion it is due to:—

1. Insufficient or impure alum.

2. Alkaline bath.

The hardening action of alum is due to the aluminium sulphate and some grades do not have the correct proportion. Alkaline baths harden gelatine slowly because alum hardens best in an acid solution.

It is false economy to overwork the fixing bath. The difficulty is in knowing when the limit of the bath has been reached. By experiment the writer has calculated that each ounce of a solution of acid hardening fixing bath containing 50 per cent. solution of hypo should fix twenty-five square inches of plate surface.

Directly over the fixing tanks he has fixed an ordinary slate with a pencil attached to a string. The two sizes of plates in use are 5 × 7 and 8 × 10, and their areas are 35 and 80 square inches. As each tank or batch of plates is developed notation of the number of square inches is placed upon the slate. Our tanks hold one gallon each, and, therefore, when the total surface area fixed is approximately 3,200 square inches, the bath is discarded and a new one made up. If only one size of plate is used the record is kept more easily. This may seem to be too much trouble, but once you are accustomed to it, it is very simple, and if plates are fixed for 20 to 30 minutes in a bath, which is correctly compounded and not overworked there need never be a stained or faded negative. Those of us who have lost good negatives from these causes should appreciate the value of their elimination.

CARROLL B. NEBLETTE.

AT-HOME PHOTOGRAPHY.

FROM time to time, sidelights on this profitable branch of photography appear in these pages, and are of undoubted value to those who read. In view of the importance of at-home photography, however, a general review will not be superfluous.

Everyone will not go to a photographer, and if we leave things at that, it means that quite a large slice of humanity is of no use to the profession. But of those who won't go to the photographer, many will not object to the photographer going to them, and some will be only too delighted to welcome him. In the course of a fairly long experience, I have never deliberately sought this class of work, being fully occupied in other directions, but even so I have met a continual demand and numerous openings for it, and, in my opinion, trade which comes to one unasked should flourish for anyone caring to cultivate it.

The first essential for successful at-home work is what I might call a "personable" disposition. The individual who cannot stroll into a stranger's mansion or cottage and make himself and his tackle quite at home, and do it without gush or offence, is handicapped to start with. To make a good impression on the client and to be able to work in comfort under difficulties, one must be neither rude nor timid. It is not always easy to study one's camera position and the customer's carpet in the same breath, but it will not do to sacrifice either.

An assistant, if not absolutely necessary, is very valuable. He or she need have no photographic knowledge. Sufficient intelligence to be able to carry out simple instructions, is quite enough.

The time of day, in its relation to the lighting of distant places, has been treated exhaustively by Mr. D. Charles, and his device for ascertaining the direction of the sun's rays at any place at any time has been published in this Journal. This, the weather, train times, and suchlike details should all be thought of when negotiating with distant clients.

The correct equipment to take to an at-home engagement will depend largely on the job and on the operator. I have found a triple-extension field camera with a light but strong tripod to be worth its weight more often than not. For carrying a field camera, I think an attaché case much better in every way than a canvas bag. It is neat, waterproof, and capable of standing a knock or two without the contents suffering. A folding tripod can be strapped along the bottom of such a case and the lot carried without any great exertion. For cameras larger than half-plate, a suit case would be the equivalent. The advantages to be derived from the possession of a small camera have already been described and emphasised, and I can endorse all that has been said in the small camera's favour. But one point should not be overlooked. A small camera alone is not at all impressive with the average customer. Something large and unwieldy looks professional, while the vest pocket or quarter-plate even if it cost ten or twenty guineas looks too much like a toy, particularly with clients who are in the habit of playing with this kind of "toy" themselves. Even though the small camera does most of the work, a larger camera should always be in evidence, though it might be feasible to camouflage a vest-pocket folder to look like a 10 by 12 outfit!

For half-plate work lenses of about 7 and 13 inches focus will cover most things. Anastigmats are not absolutely essential for at-home work, though this type of lens has the advantage of speed which is often needed in dark interiors. Much can be done with a good R.R., however. Single lenses are not much use unless one is taking busts, when excellent results can be obtained with them if the diaphragm is made large enough to be equivalent to about $f/8$, the sitter being posed in a window. Large single lenses can be picked up in brokers and pawnshops for a few shillings, but apart from this use—for which they were not designed by the way—they are no use for at-home photography.

After using numerous brands of plates and film I have found it extremely easy to get first-class negatives on Guilleminot's Radio-Eclair and Eastman Portrait Film; but I must add, in justice to other plates and film, that I have yet to find one that will not give good results for the proper treatment. As to a choice of developers or developing methods, every man has his own pet ideas, and with regard to the avoiding of halation, harshness and other evils, enough has been written to satisfy everyone's requirements. I agree with the view that amidol is very good when under-exposure is known to have occurred, and that pyro formulæ most readily give negatives for the "slow-development" papers, but more than this I will not include here.

When portraiture is the object of an engagement, it is wise to take with one a background and reflector. These should be as small and light as possible for the sake of smooth handling in the customer's drawing room. A double-sided, plain, or nearly plain, background is the most generally useful; and the reflector, which need be nothing more elaborate than a couple of yards of linen, is best held by the assistant, though a light frame for the job can be bought or made. Shutters for this sort of work are superfluous if working indoors, as very short exposures are not advisable or of use; but for taking children or animals on the lawn, a shutter is an advantage. I favour a studio type such as the Guerry or Packard Ideal. The former, though perhaps never intended for outdoor work, has the advantage in the open of forming an excellent sky shade. The Packard Ideal is a very delicately balanced piece of mechanism which will give time, bulb or instantaneous exposures without any setting. When one is used to it, this shutter is almost human in the way it can answer the slightest pressure of the operator's hand. I may arouse disagreement in not restricting myself to focal-plane or other graduated shutters, but from experience I consider the studio type to be the more satisfactory for all work other than high-speed snapshotting.

Last but most important is the matter of prices. Unfortunately, there is no recognised scheme for charging on at-home or any other kind of outdoor photography, and if anyone were to draw up a list there would be little hope of it being universally adopted. If the photographer works for one class of people only there should be no difficulty in settling prices. They will depend on the styles and sizes of his work, the kind of people he deals with, and the outside expenses incurred. When there is no restriction as to the class of customer a fixed list will not serve without modifications. For example, one could hardly charge on the same scale when taking photographs for a middle-class artizan as when working in the grounds of a Bishop's palace, and there are plenty of places where both classes of work would be available to the same photographer. Whilst saying this, however, I do not mean that wealth should of necessity be plundered, but that a higher rate, accompanied by a higher standard of work, will pay much better and be more satisfactory to all concerned when the customer is a high-class one. Outside expenses, such as train fares, the length of time one is away, meals, etc., must not be a loss to the photographer, but at the same time they should be charged up with an eye to the effect on the client. No matter how important a person he may be, he is hardly likely to relish paying more for a man's time and journeying than he does for the photographs, and if he is a customer worth keeping it may be as well to keep the outside expense as inconspicuous as possible. It is not a bad plan to submit an estimate for the job, the charge to include one copy of each of so many exposures, further copies to cost so much. Details of travelling expenses, if necessarily large, need not be set out in particulars.

An important point for the man who does not practise outside work regularly is to make reasonably sure of payment before going to expense. In my first experiences of at-home engagements I have lost rail fares and half-days, to say nothing of plates and work. Now I am more careful. It is difficult to say, "Don't give any credit," since many good customers are not kindly disposed to the business man who does not seem to trust them. The best plan is to discriminate; a personal interview with a prospective client is advantageous. If there is every prospect of the account being settled without recourse to the courts, payment is best not suggested at all until proofs have been furnished. In this way, larger orders than have been hoped for may accrue. But the reliable customer will nearly always mention the question of expenses if the scene of operations is any distance from the photographer's headquarters, and a deposit should not be refused from a stranger. Working for people in moderate circumstances and at no distance I have found the following plan serve excellently. I make no mention of expenses at all, but quote prices that will not leave me at a loss. No cash is asked for, the customer being told that payment is not essential until proofs are shown. Then, if the party is known to me and I am sure of a straight deal, the order is completed with or without payment; but in other cases an invoice marked "Terms strictly C.W.O.," is forwarded with a note of thanks for the order, also a definite statement that the order will be delivered within so many days after the return of invoice. Since working on this system, I have only been done once, and that was by a life-long friend. Admittedly the "C.W.O." touch may look more like commercial manners than professional etiquette, but when the former means a profit it is preferable to the latter at a loss.

THERMIT.

DESENSITISING WITH POTASSIUM IODIDE, FREUND'S METHOD.

THE most recent work published on the above subject is to be found in two papers by one of us ("Journ. Soc. Chem. Ind.," Vol. 39, No. 12, p. 156T reprinted "Brit. Journ. Phot.," 67, pp. 447 and 463, and in more detail in "Phot. Journ." 1921, 61, 12-15), so that we naturally read Mr. Bolas' article, "B.J.," September 9, pp. 532-4, with interest.

There are many points in it which invite criticism, but we will confine ourselves to a description of some experiments we have just made with the object of testing some of his statements, and to an invitation to Mr. Bolas to produce evidence in support of them, and of the rather remarkable theoretical views he places on record.

The article is apparently only intended to revive interest in an old process which hitherto has failed to find any useful practical application, but if Mr. Bolas' statements are justified, he must have obtained better results than other experimenters, and he should give us fuller details, so that the whole subject can be thoroughly worked out and applied in practice.

The following series of experiments were made on Ilford Empress plates. A number of plates were given identical exposures in a sector-wheel machine (one slow revolution) to the light from a controlled metal filament lamp at 1 metre distance, all the strips being cut from quarter-plates taken from the same box. After exposure, the plates were treated as follows:—

Nos. 1 and 3. Treated for two minutes with 4 per cent. pure colourless potass. iodide solution: 2 grs. cryst. sodium carbonate were added to the 25 *ozs.* batch as an extra safeguard (*vide* Bolas' article).

No. 2. Same iodising solution as above, to which one-tenth its volume of 10 per cent. potass. bromide solution was added before use. Treatment, two minutes.

No. 7. One minute only in same solution as 1 and 3.

Nos. 4 and 5 were iodised in the solution recommended in "Photographic Journal," 1921, 61, p. 13, and containing 1 per cent. sod. meta. disulph., 2 per cent. neutral (cryst.) sodium sulphite, and 3 per cent. sodium thiocyanate, for five minutes.

After iodising, the plates were well rinsed for about two minutes in repeated changes of water, which, in the case of Nos. 4 and 5, contained 2 per cent. neutral sodium sulphite.

No. 6 was not iodised, and was developed in pyro soda (Ilford formula) without bromide for four minutes. Bolas' developer, made up exactly as recommended on page 533 of his article, was used for plates 1, 2, 3, 5, and 7, No. 3 being developed in artificial white light, while plate No. 4 was developed in the alkaline amidol developer recommended in the above "Photographic Journal" paper by one of us. All except No. 3 were developed in darkness. In all cases, except No. 6, ten minutes' development at 70 deg. F. was given, and a neutral "hypo" bath 1:4 was employed for fixation.

The following table shows the resulting densities:—

DENSITIES PLUS FOG.

Plate	1	2	3	4	5	6	7
Exposures (relative)							
Fog	.03	.03	.06	.16	.04	.02	.04
1						.18	—
2				.25		.32	—
4				.36	.12	.65	—
8	.08	.06		.51	.23	1.14	.08
16	.14	.14	.11	.70	.39	1.70	.13
32	.24	.23	.17	.97	.55	2.21	.21
64	.30	.30	.26	1.32	.71	2.66	.31
128	.38	.40	.35	1.81	.84	—	.41

The results show clearly that, in our hands, ordinary development of the untreated plate (No. 6) gives the best result, iodising with the hyposulphite-thiocyanate mixture comes next (4 and 5),

the amidol sod. carbonate developer (No. 4) bringing out far more in a given time than Bolas' hydroquinone developer (No. 5). The values in columns 1, 2, and 7 indicate that it makes no practical difference whether the Bolas iodide solution is allowed to act for two minutes or one minute, or whether bromide is added or omitted.

No. 3, which is the worst, shows the further loss of image resulting from development in white light, whereas many experiments with the iodiser used for Nos. 4 and 5 have shown us that, after rinsing in several changes of dilute sulphite for two minutes, there is no further destruction of the latent image when development is carried out in white light; the plates may even be dried and kept for a week, and possibly much longer, without further loss.

In conclusion, we should be glad if Mr. Bolas would state what evidence he has in support of the statement in paragraph 3 of his article that the process depends on the *partial* conversion of the silver bromide to iodide in the unexposed parts, *while the exposed parts undergo little or no change*. If this were true, it should be possible to demonstrate it by fixing out the unchanged silver bromide from the iodised washed plate in a hypo solution, or, better still, in a 10 per cent. solution of aluminium sulphocyanide, in which the solubility of silver bromide is stated by Valenta to be over 200 times that of the iodide. Our tests of iodised plates with both these solvents entirely failed, however, to discriminate between the exposed and unexposed areas.

On consulting Meldola's article in Watts' "Dictionary of Chemistry" we failed to find the word "gelatinobromide" used in connection with the reversing action of iodides on photographic plates, while his book, "The Chemistry of Photography" (1904 edition, p. 217), refers only to this effect in connection with the wet collodion process.

It would interest us to know wh- Mr. Bolas states that "the photolyte being uncoloured, it is by no means surprising to find that the red light of the dark-room may have in this case a very considerable action," unless his statement is founded on the article in the "Photographic Journal" already cited, in which it is shown that very dilute solutions of iodides are able to confer red sensitiveness on gelatinobromide of silver.

The theoretical views put forward by Mr. Bolas, including the explanation, due to Meldola, of the reversing action of potassium iodide in the light, appear to us to rest on very slender foundations, and to require much further experimental support before those who hold different views are asked to accept them.

O. F. Bloch, F.I.C.

FORTHCOMING EXHIBITIONS.

September 19 to October 29.—Royal Photographic Society. Secretary, Royal Photographic Society, 36, Russell Square, London, W.C.1.

November 17 to 19.—Bowes Park and District Photographic Society. Particulars from the Hon. Sec., S. Smith, 68, Mannock Road, Wood Green, London, N.22.

November 23 to 26.—Rotherham Photographic Society. Latest date for entries, November 9. Particulars and entry forms from the Hon. Exhibition Secretary, Sydney G. Liversidge, "Orissa," Gerard Road, Rotherham.

December 3 to 17.—Scottish Photographic Circle. Hon. Secretary, W. S. Crocket, 10, Parkgrove Terrace, Tollcross, Glasgow.

1922.

January 21 to February 4.—Partick Camera Club. Particulars from the Hon. Secretary, James Whyte, 51a, Peel Street, Partick, Glasgow.

February 14 to 17.—Exeter Camera Club. Particulars from C. Beauchamp Hall, Hon. Exhibition Secretary, Exeter Camera Club, "St. Denys," Bellevue Road, Exmouth.

February 11 to 25.—Scottish Photographic Salon. Particulars from the Secretary, James F. Smellie, Braefindon, Allanshaw Street, Hamilton.

Cambridge Photographic Club.—At the annual meeting of the Cambridge Photographic Club held last week, Mr. J. Winship was elected to the presidency and the retiring president, Mr. E. C. Ogle, to the treasurership, and Mr. W. Farren was re-elected secretary. The reports of the secretary and treasurer showed that the Club was in a flourishing condition both numerically and financially.

A MODERN PROCESS AND COPYING CAMERA.

A popular but interesting account of a new camera installation, recently established by the United States Geological Survey, appears in the current issue of the "Scientific American." It will be seen that the installation, which has been designed by Mr. A. H. Linsenmeyer, chief photographer to the Survey, is distinguished by elaborate electrical methods of operation, and particularly by an electrical device indicating the setting of the optical system to a given scale of reproduction. As in the case of the installation employed by the Egyptian Survey Office, and fully described in "B. J.," August 20, 1920, pp. 511-513, the sensitive plate is placed in the dark room itself.

The three-and-a-half-ton giant, hanging from the ceiling, dispenses with the perplexing problems of alignment, focussing, etc., and responds to direction by electricity or by hand more readily than does the tiny Kodak to the grasp of a steady pair of fists. Nowhere are higher standards of accuracy maintained than in the Federal Survey, and that absolute scale is secured in the reproduction of every map is due largely to the fact that the big machine is exact in every movement to the smallest fraction of an inch.

Save for the bellows and curtain-slide, which are of rubber, the camera is an all-metal affair. A rigid tubular steel frame, ten by sixteen feet, is suspended from the ceiling by springs so attached as to offset any possible vibration of the building. From this

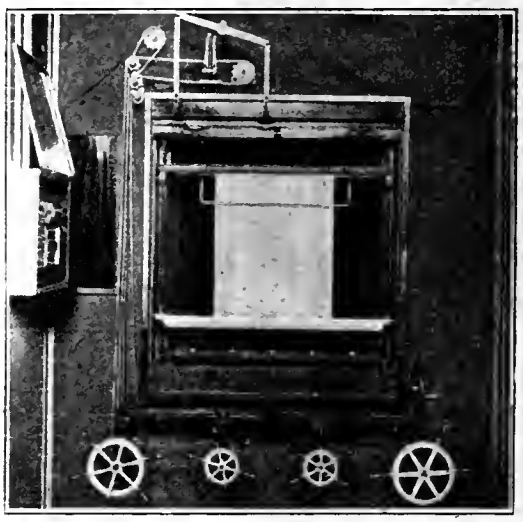

Plate-holder seen from behind the instrument inside the dark room.

massive frame hang the several parts of the camera, in the operation of which the usual method of copying is reversed. In one corner is the plate-holder, placed inside the dark-room. In front of this is the bellows, terminating in lens and prism, attached to a carriage which moves on two parallel rod-rails. Resting on this carriage and travelling at right angles is a second carriage supporting the copy-holder. And here is where the process differs from the ordinary practice; the lens and copy-holder move toward or away from each other, according to the size and scale of map desired, but the plate-holder remains stationary inside the dark-room. This dispenses with the constant squaring up of camera and copy-holder and practically eliminates the time-consuming operation of focussing. The lens is moved forward or backward by the motion of the first carriage, which opens and closes the bellows in accordion-like fashion. The uniformity of bellows movement is regulated by lazy-tongs on each side which give the camera front the appearance of a huge jack-in-the-box.

As previously pointed out, the plate-holder of the machine is firmly attached to the main frame and extends into the dark-room. It has an automatic plate-centering device, aluminium drip-trough, half-tone screen-holder, screen-distance-regulator, spring support for holding the plate in position, and a rubber curtain which keeps out the light during exposure. Just beneath the plate-holder are four hand-wheels which make one think of a pilot-house. Two of the four actuate the lens, giving it horizontal or vertical motion. The

others move the bellows and regulate the copy distance. All four wheels are connected by chain gear to square revolving rods, along which slide bevel gears, an assembly which permits motion to be communicated to the gears at any point in their travel. And if the photographer chooses to operate the machine from the dark-room, he can peep through a little red window and watch the copy-holder and lens swing into position for the picture.

The copy-holder is a steel frame carrying two heavy glass plates, four by six feet. The copy is placed between them; but perhaps you are wondering how, for the illustration seems to have them permanently fixed. This is true as regards the front plate, which is ever in correct alignment with the lens and plate-holder. The rear glass, however, drops back from the top, bookwise, when you turn a hand-wheel at the side of the frame. This releases eight felt-covered cams (four on each side of the frame) and when the copy is inserted, either from the top or from the side, the wheel is again turned and the rear plate is jammed against the front. If perchance the copy should fall between the glasses at the bottom, the operator can "fish" it out with a specially designed rod which grips the edge of the paper without injuring it. The construction of this plate-holder makes it possible to copy directly from tracings and whatnot and renders

Operating the new prismatic-process copying-camera from the electric switchboard.

easy the making of positives and transparencies—those beautiful pictures on glass for which the Geological Survey is famed.

A curtain made of nearly transparent material wound on a spring roller at the back of the frame is employed to get the desired lights and shades. Another unique feature of the copy-holder is the centering device. This consists of four cords, two of which cross the plate vertically and two horizontally. They are manipulated by a slide at the top of the holder which, moved toward either end of the frame, gives the exact margins for the sheet to be photographed. A slide-rule, perfected for this machine, determines at once the size of plate to be prepared for exposure without the usual measurement on the ground glass.

Focussing is a simple process. There are two scales, one on each carriage, on which the degree of reproduction is indicated, and the two carriages are moved until the figures read alike on both scales. That is the thing in a nutshell, but in detail it is worked out like this. An electric contact is set at the desired point on the scale of the copy-holder carriage which, with another contact, is then put in motion. When the two points meet and the circuit is completed, a small incandescent lamp flashes the signal to stop, that the copy-holder is in exact position. Should it happen that the carriage runs past the point of contact, the operator uses a fine adjustment hand-wheel to bring it back, when the little lamp will again send out its glow. The photographer then turns his attention to the primary carriage with the lens and prism. He sets the scale, corresponding to that on the other bar, and starts the motor which drives the carriage along until the proper figure is reached, again using a hand wheel for accurate adjustment. It is all so easy that the picture-maker can be up and away to another job while his friend with the ordinary copying camera is fussing and fuming over details.

Reversible motors drive the two carriages with astonishing ease and precision. As has been stated, the copy-holder is always in correct alignment with the lens and plate-holder, so that the camera front never budges a hair's breadth unless the copy-holder moves in the same direction, but both can at once be driven forward or backward as occasion demands.

Cooke lenses of 31 and 42 in. focal length are used in combination with a Cooke prism. These, attached to a heavy brass plate, will make a picture large or small. As accuracy is the paramount consideration, the optical parts must be in just the right position and absolutely rigid. Plate and copy-holder are plumb or, if not, can be made so by screw movements on each part, while the prism is brought into alignment by a thumb-screw passing through a strong brass bracket which runs out beneath it from the front-board.

Patent News.

Process patents applications and specifications—are treated in "Photo Mechanical Notes."

Applications, October 3 to 8:—

APPARATUS. No. 26,552. Photographic apparatus. G. W. Cooper and Stereo Kinema Syndicate, Ltd.

RELIEF PHOTOGRAPHS. No. 26,128. Process for producing relief photographs. E. Howard.

LENSES. No. 26,629. Lenses for photography, etc. Kapella, Ltd., and H. W. Lee.

FOCUSSING DEVICE. No. 26,188. Roll-film focussing device. A. E. and V. C. Perry.

STEREOSCOPY. No. 26,429. Single-picture stereoscope. A. E. Stanley.

COLOUR PHOTOGRAPHY. No. 26,509. Photographic cameras for reproducing objects with their natural colours. G. Russo.

PHOTO MICROGRAPHY. No. 26,486. Apparatus for photographing microscopic objects with an ordinary camera. F. Stanley.

COMPLETE SPECIFICATIONS ACCEPTED.

These specifications are obtainable, price 1s. each, post free, from the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C.

The date in brackets is that of application in this country; or abroad, in the case of patents granted under the International Convention.

DRY MOUNTING FLATIRONS.—No. 169,036 (July 2, 1920). According to the invention the fixing iron comprises a single gas tube upon which is mounted a handle. At one end of this tube is attached a control tap with nipple connected by a flexible tube with any convenient gas supply. The operating head, which is of the more or less hollow type, is secured to or forms a part of this tube. An ordinary gas nipple is fitted midway within the tube, or for convenience the tube may be broken at this part and united again by the nipple. Immediately in front of the nipple the tube is cut away at the sides and has a number of perforations, permitting of an outward supply for the gas issuing from the nipple, and that

Fig. 1.

portion of the tube between the perforations and the hollow head serves as a combustion chamber.

In the drawings A is the body portion of a gas conduit, comprising a single tube upon which is mounted a handle B fixed by washers C nipped against the shoulders D of the fixed collar E and the flange F of the burner or nipple G when securing the head section H of the tube to the section A. The bore B' of the handle B is larger than the tube A so as to leave a suitable

clearance and prevent the possible heating of the handle B. The sections A and H of the gas conduit are coupled together, preferably by the nipple or burner G, one part of which screws into A : the other part screws into H with the flange F acting upon the washers C as before described. The tube or section H forms the combustion chamber J upon which is preferably cast the operating head K; or the head may screw thereon, as desired. The tube H has a cut away portion or a number of spaced open

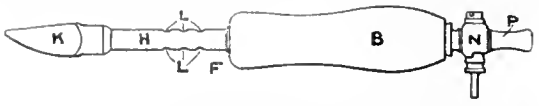

Fig. 2

ings L on opposite sides in advance of the burner G, the distance between each pair of these openings being predetermined, and representing in the corresponding length of flame a variation in its heating capacity to an extent approximating 50 degrees F. The combustion chamber J opens into the hollow part of the head K, which may vary in size and shape and be formed by boring or coring according to whether the head is detachable or cast upon the part H. An exhaust port M is provided in the head K for the escape of the waste heat or hot air in the chamber J. N is a control tap attached to section A for regulating the supply of gas to the burner G, and P is a nipple formed thereon to which is secured the flexible gas supply tube, not shown.

When about to use the device the gas is turned on at the tap N : the small jet issuing from the burner sucks into the com

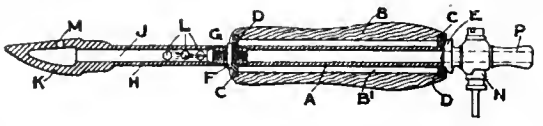

Fig. 3.

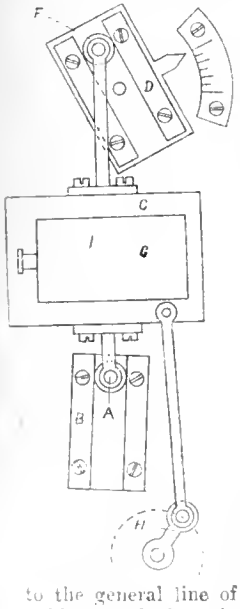
bustion chamber J atmospheric air through the cut away parts or the holes L, so that upon a light being applied the mixtures ignite. The resulting flame will extend as far as the last pair of holes and give a maximum heat for quickly heating the head to the desired temperature. When this is attained, the tap N may be adjusted to reduce the flame in order that the desired temperature of the head may remain constant throughout the use of the device. Any variation in the length of the flame amounting to the length of the cut away part or to the distance between each pair of holes L will lead to a variation in heat approximating to 50 degrees F.—John Goodrick, 52, Hare Street, Halifax, Yorkshire.

Stereo-Cinematography.—No. 165,587 (April 22, 1920). The invention relates to means for imparting a stereoscopic effect to pictures presented on a cinema screen, and consists in the mechanical means employed for giving transverse reciprocating movement to the camera while at the same time keeping the lens axis directed on the subject.



Reciprocating motion is applied to the camera by means of a crank and connecting rod, operated by a handle through suitable gearing; the periodicity of the reciprocating motion being varied in relation to the speed of the handle by variation of the gearing.

The handle may be made to also operate the photographing mechanism of the camera through a chain, gearing, or flexible wire.

The distance through which the camera reciprocates may be varied by variation of the radius at which the crank pin, of the crank imparting the reciprocating motion, works.

In the drawing, which is a plan view, the pivot A on the camera platform C (or an extension thereof) has a reciprocating motion on a straight line directed by the guide B mounted upon the base K; the reciprocating motion being on a line at (or having a component at) right angles to the general line of direction of the camera G.

If now during the reciprocating motion of the pivot A the camera platform C is given a certain small angular motion about the pivot, the camera, whilst being moved from side to side, will be continuously pointed upon a distant object.

A roller guide block F is mounted upon the camera platform C (or an extension thereof), and is directed on a straight line by the guide D, the latter being mounted upon the base K on a line at an angle to the line upon which the guide B is set.

An angular motion will then be imparted to the camera platform C about the pivot A depending in magnitude on the magnitude of the angularity of the guide D; the distance of the object upon which the camera will be directed being indicated upon a scale, this scale reading being varied by variation in the angularity of the guide D.

The crank H may apply motion to any point of the camera platform C (or extension thereof) as may be convenient.

The crank may be mounted upon the base K as shown, or it may be mounted upon the camera platform C; and it may be mounted horizontally or vertically.

The base K is fixed to the camera tripod or stand.

It will be seen that the action of the apparatus, in producing the combined reciprocating and converging motions, will be the same if the construction hereinbefore described be reversed, that is to say, if the guides B and D were mounted upon the camera platform C, or extension thereof, and the pivot A and the roller guide block F were mounted upon the base K or extension thereof; all parts being placed relatively to each other as in the first, or primary arrangement.—Alfred Reginald Boorman, 130, Francis Avenue, Southsea, Portsmouth.

Trade Names and Marks.

MARKS PLACED ON THE REGISTER.

The following marks have been placed on the register :—

Aerozon.—No. 412,022. Spraying machines included in Class 6. The Aerograph Co., Ltd., 43 Holborn Viaduct, London, E.C.1, manufacturers of spray painting plant, air compressors and general engineers.

Tender for Aerial Cameras.—The Department of Overseas Trade is informed that the Venezuelan Government wishes to obtain tenders for three sets of photographic apparatus for topographical work from aeroplanes. Applications should be made to the Venezuelan Minister in London, Dr. P. C. Dominici, 7, Richmond Mansions, Earl's Court, S.W.

R.P.S. Scientific and Technical Group.—At the meeting to be held on Tuesday next, October 25, the following papers are to be read :—"The sensitivity of silver halide crystals which are geometrically identical," by F. C. Toy, M.Sc., A.Inst.P.; "The darkening of silver bromide grains on exposure to light as further evidence of their heterogeneity in photographic emulsions," by J. Brooksbank, A.R.C.Sc., B.Sc.; "The uniform development of dry plates," by O. F. Bloch, F.I.C.; "Experiments relating to the rendering of gradation in photogravure," by H. Mills Cartwright.

The Picture Postcard Trade.—Strong efforts are now being made to secure a reduction in the postage on picture postcards. The increase to 1½d. is said to have caused a decrease of 50 per cent. in sales. A well-known picture postcard producer says he is assured that the Government has the subject under consideration. He asks that the rate should be reduced forthwith, or at an early date, so that publishers will be able to save the export market for next year. The immediate result of the three halfpenny postage has been that stocks have been left on the hands of publishers, wholesalers and retailers.

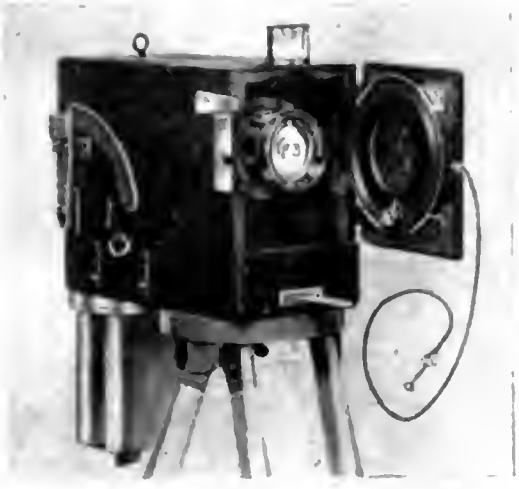
Scottish Photographic Salon.—The attention of our readers who are interested in pictorial photography is directed to the fourteenth annual salon of the Scottish Photographic Federation, which will be held in the Parish Halls, Hamilton, from Saturday, 11, till Saturday, February 25, 1922. Sir Henry S. Keith is the honorary president, and the Board of Selectors is as follows : Messrs. Arch. Cochrane, Barrhead; Robt. Chalmers, Sunderland; and J. Campbell Harper, Edinburgh. Full particulars and prospectus from the secretary, James F. Smellie, Braefindon, Allanshaw Street, Hamilton.

New Apparatus.

Aptus Automatic Ferrotype Cameras. Made by Moore and Co., 101-103, Dale Street, Liverpool.

THE inquiries which frequently reach us for particulars of "while-you-wait" cameras for outdoor use in the streets and at seaside and other pleasure resorts, indicate the large amount of photography of this kind which is done. Cameras of American make, some of them in the form of a cannon, have been supplied in this country in the past, but Messrs. Moore are now the makers of a series of excellently designed and constructed cameras for this branch of work. In each model the camera is loaded with a magazine containing 100 ferrotype plates, and is provided with a tank allowing of the plate being simultaneously developed and fixed immediately after exposure and delivered to the customer within one minute. The lens, in models A, B and C, is fitted with two diaphragms, and with simple shutter, and in all three models with a focussing scale allowing of portraits or groups being taken at distances within 2 yards to 12 yards from the camera. The lens is set in focus on any given distance by pulling out to the required extent the brass bar seen immediately above the tripod head in the photograph. Direct-vision finder also is fitted for sighting the subject on the plate.

A pneumatic device is used for holding each plate in position for exposure. By turning down the upright lever seen at the back of the camera to the lowest point of the curved guide bar a rubber mouthpiece is brought down on the back of the top plate contained in the magazine. A plunger, operated from beneath the camera, presses the plate against the mouthpiece, a rubber bulb connected with the mouthpiece being first pressed. On releasing pressure and bringing back the bar to the upright position, the plate is brought into position for exposure. It is transferred to the developing tank by a slight pressure on the bulb, the plate being guided directly into the vertical tank seen below the camera. This tank is made in two divisions and rotates, so that by turning it the part into which the plate has been delivered is brought round for removal of the developed and fixed portrait whilst the second part is placed for the reception of the next exposure. The finished plate is then lifted out of its tank by means of a small horseshoe magnet. The whole apparatus is most solidly and substantially

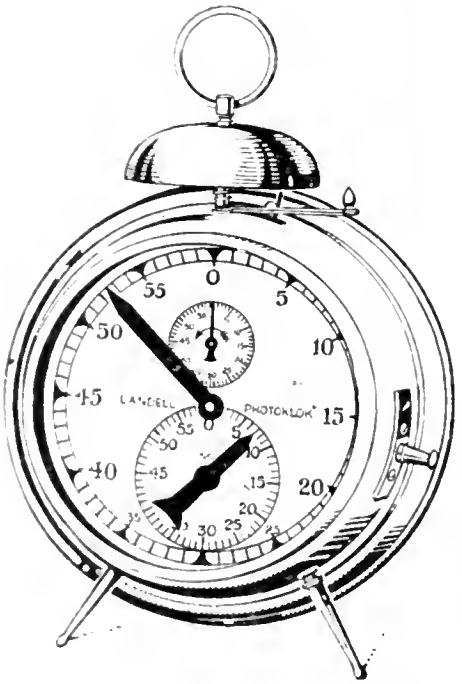


made and of attractive appearance. In the A pattern, for pictures 2½ x 1¾ inches, the price is £6. The B pattern is similar, but has a revolving back by which upright or horizontal pictures may be taken. The price is £8. The C pattern takes the two sizes, 2½ x 1¾ inch and 3½ x 2½ inch, and is also fitted with revolving back. The price is £12 10s.

The De Luxe model, illustrated (for 2½ × 1¾-in. plates), is fitted with a British anastigmat lens of *f* 3° aperture, and everset diaphragm shutter with Antinous release. This model is fitted with revolving back and is sold for £18. It may also be obtained to take the two sizes of portrait already mentioned at the price of £25. Messrs. Moore supply the ferrotype plates in these two sizes in 100, 500, or 1,000 lots, and also the necessary developing and fixing powders and mounts for the metal portrait plates.

The Landell Dark Room Clock. Sold by Lingwood and Lowen, 10, Chadwell Street, London, E.C.1.

HABITUAL users of a clock in a dark-room for factorial development and for other purposes in timing photographic operations, would seem to be fast [illegible] people, otherwise it is scarcely possible to find



an explanation for the successive issues on the market of a considerable number of patterns of clock. The present introduction, a combined French and English make, embodies a range of facilities such that the most exacting user of a clock can hardly ask for more. As shown in the drawing, the clock has three separate dials. That arranged on the outer circumference of the face record minutes from 0 to 60, moving just like the large hand of an ordinary clock. The smaller dial in the lower part of the face is provided with a seconds hand, the finger traversing the dial in one minute. The small upper dial is the setting for the alarm, which it will be observed, may thus be set to ring at the termination of any given interval of time up to one hour. On the right hand side of the clock is the stopping and starting lever, and immediately under the gong a second lever which silences the alarm, if so required. The drawing does not exaggerate the boldness of the dials, an important feature nowadays in a dark-room clock when the latter has frequently to be used in dim illumination. In operation, the clock is exceedingly simple. For example, in case of factorial development the clock is stopped with the seconds hand at 0, and the minute hand also at 0. After pouring on the developer and simultaneously starting the clock, the number of seconds to the appearance of the image is then noted on the lower dial. By multiplying this time by the factor of the developer, the total time of development is ascertained and the alarm can then be set to this time on the upper dial, and development continued without further attention until the signal is given for the plate to be taken out. The clock is evidently exceedingly well made and of nickel steel finish. Its price is 25s.

A NEW DISH ROCKER. Mr. H. W. Harrington, 43, Ellesmere Avenue, N.C.R., Phœnix Park, Dublin, sends us a simple form of dish rocker for the dark-room, which he is supplying, price 4s. 6d. each post free. The rocker consists of a wooden frame on which pivoted on a horizontal axis, a wooden platform for the developing dish. The platform being free to rock over a small angle by

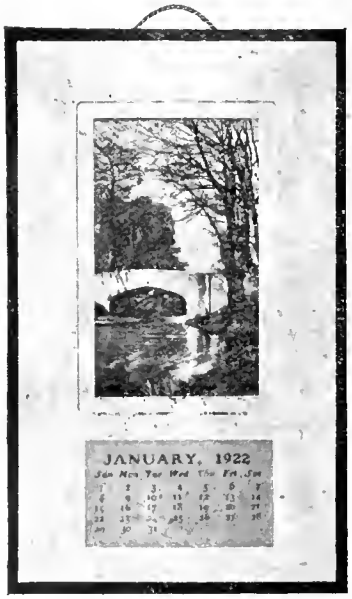
the operation of the finger, the solution in the developing dish is readily kept in constant movement. The device is an extension of the old dodge of laying a split lead pencil on the working bench midway under the developing dish, but, of course, the rocker is an improvement on this primitive plan, since the axis on which the dish is rocked is made a fixture.

New Materials.

Artist Passe-Partouts Mount-Frames. Made by W. Butcher and Sons, Ltd., Camera House, Farringdon Avenue, London, E.C.4.

Messrs. Butcher have produced so many different and admirable styles in ready-made passe partouts that it is not the easiest thing

to find fresh comments to make upon their latest series. However, those which have just been issued as the "Artist" are characterised by an excellent simplicity which fits them for almost any



description of print. The cut-out behind which the print appears is of matt white card, whilst the binding strip is black. The result, in conjunction with a plate mark round the opening of the cut-out, is of most refined appearance. For the benefit of those unfamiliar with the previous issues of these passe-partout frames, let it be said that the print has simply to be laid behind the cut-out and a card backing secured against it, by moistening and pressing down a gummed flap. The passe-partout is then complete without any of the trouble of applying the gummed paper binding. The present "Artist" series includes eight different sizes, four for upright postcards, quarter-plates, No. 1a F.P.K. and C.d.V.; the other four, for the foregoing sizes, but the "landscape" way of the prints. The prices range from 1s 3d. to 1s. 6d. each.

In a companion series Messrs. Butcher embody in the passe-partout a removable calendar immediately below the print, as shown in the second illustration. This calendar series provides an eminently welcome and agreeable form of photographic Christmas greeting card. The prices of the calendar series are from 1s. 9d. to 2s. each As we have said on the occasions of noticing the earlier styles of Messrs. Butcher's passe-partout mount frames, these articles provide a most neat and tasteful means for the display of photographers' window specimens, and have the special merit of keeping the latter clean and allowing of their being regularly changed. Moreover, the display of prints in this form is an inducement for sitters to purchase portraits framed in the same style.

Christmas Card Mounts.—Messrs. Jonathan Fallowfield, Ltd, 146, Charing Cross Road, London, W.C.2, send us samples of the Christmas card and calendar mounts which they have in readiness for the forthcoming season. The cards include a variety of styles, most of them of the folder pattern, and of the slip-in type; a few, however, are for mounting of the prints or for insertion of a print by a touch of adhesive along one side. We observe a commendable diversity of styles appropriate to the variations of taste among the public. The purchaser from Messrs. Fallowfield may obtain mounts in quiet grey, buff or cream colour with a minimum of embellishment, or, on the other hand, those with a cheerful design in bright colours, including the time-honoured sprig of holly. The calendars, in particular, are exceedingly choice examples of mount-making, and are obtainable in sizes from V.P.K. to postcard in both upright and horizontal patterns. Messrs. Fallowfield hold a large stock of these mounts, and can execute orders for them without delay.

Meetings of Societies.

CROYDON CAMERA CLUB.

Mr. B. J. Rose, of mechanical genius, produced "More Chips from a Workshop." One of the most energetic and youthful members of the club in all but years, he confessed, a little sadly, to three-score and ten. Truly, "those whom the gods love die young," for the genial demonstrator in spirit will never grow old.

He spoke, he said, subject to the good behaviour of a new set of false teeth, which he had found endeavoured to part company on the first sign of rhetoric on his part. Also, the ball of a cistern ballcock, in some mysterious way, had disconnected itself in the dead of night, and a veritable flood in his workshop was the result.

Ostensibly for the benefit of new recruits, he then narrated the special talents of many older members, some of whom appeared slightly embarrassed during the complimentary recital. Luckily the topic was inherently limited, and he soon passed on to a plain exposition of the right and wrong way to use familiar tools. Following, came the transformation of old cocoa-tins into hinges, flour-dredgers, combined nut-graters, and super skin-titillators, match-holders, and other useful articles of the Sixpenny Bazaar nature. There was no deception, the mighty deeds were wrought in front of all. An aeroplane wing, purchased for five shillings, had furnished 7 gross of screws, and a variety of elegant furnishing contrivances. The examples shown were of the sort usually described as "occasional," possibly because they are not invariably in the way.

After other ingenious excursions, Mr. Rose exhibited a focussing pinhole camera, which, he carefully explained, was always in focus. This somewhat ambiguous way of putting things engendered no open revolt, but some *sotto voce* comment. "If the thing is always in focus, why, in all cussedness, do you want to focus?" inquired an elderly member, whose angle of view was certainly more limited than that of the pinhole. A most hearty vote of thanks was accorded for a highly practical and interesting demonstration. The teeth behaved admirably, and were a pleasure to gaze upon.

SOUTH SUBURBAN PHOTOGRAPHIC SOCIETY.—Retouching portrait negatives and the working up of landscape negatives were demonstrated before the South Suburban Photographic Society last Wednesday by Mr. Robert Coombe, of Lee. The president (Mr. P. R. Salmon), in introducing the lecturer, stated that although retouching of a sort was practised by the Daguerreotype workers, the retouching of negatives was generally believed to have been introduced in 1866 by Herr Ranbending, of Vienna, who for a long time kept his methods secret. In his earliest work he is said not to have used lead, but to have utilised the precipitate formed by adding ferrous sulphate and pyro to a dilute solution of silver nitrate, which corresponded in colour to that of the film worked upon; the precipitate was applied by means of a stump of felt or pointed pieces of wood. It was also stated that about this time Rejlander started retouching his negatives, but his methods were not made public. Mr. Coombe dealt, of course, with all the most modern materials and methods, speaking highly of Bruce's retouching medium, Kodak's matt varnish and Johnson's spotting medium. Among the many hints given to would-be retouchers were those of using a No. 3 (H.B.) pencil for general work, the scrumbling (or scribbling) touch, and a No. 3 sable with Indian ink and Payne's grey—sometimes with a touch of Prussian blue—for spotting. Many beautiful examples of retouching work, and work with the knife, were shown.

News and Notes.

PENROSE'S ANNUAL.—Messrs. Percy Lund, Humphries, the publishers of Penrose's Annual, announce that the 1922 volume will be ready on November 1 next. The price has been reduced to 8s.

AT HANDSWORTH, on Wednesday in last week, a fire broke out in the dark-room of Mr. Walter Bellamy, 112, Hamstead Road. Mr. Bellamy writes that no explanation is forthcoming of the cause other than the presence of some amateurs' films in a printing box. Neither gas or electric light were left on.

FOX TALBOT MEMORIAL FUND.—The current issue of "La Revue Française de Photographie" contains the first list of the subscriptions invited by our contemporary for the Fox Talbot Memorial Fund. The amount subscribed is 215 francs, the donors including the firms of Lumière, Lobel and Poulenc, M. L. P. Clerc, and the proprietors of our contemporary.

HOW JUDGES WORK AT EXHIBITIONS.—The methods judges adopt for allocating marks to pictures are not usually made known, but we learn from an Australian contemporary that at a New Zealand show the headings under which the 100 marks were awarded, and the maximum for each heading, were as follow: Composition, 35; technique, 25; conception, 20; treatment, 15; and presentation, 5.

A "POSITIVE" RECORD.—We have grown accustomed to the sight of suburban young ladies who spend the time travelling by tram or train to and from town in knitting jumpers, doing crochet work, or needlework of some description. But the record in this field of time-saving (says the "Daily Chronicle") was surely set up by a young lady, obviously on her way to work, who was observed walking along the sunny side of a central London street about 8 o'clock yesterday morning with a frame in each hand in which she was printing photographs!

EARLY PHOTOGRAPHY BY MAGNESIUM LIGHT.

To the Editor.

Gentlemen, Dr. Eder is at perfect liberty to dispute my translation or question the accuracy of the construction that I put upon his language; but he has no right to charge me with being profuse in the use of italics for the purpose of giving prominence to something that he never wrote. This is a very grave charge of dishonesty and deliberate falsification or, in plain language, of lying on my part.

Dr. Eder gives his own version of what he said; but to support his charge of dishonesty he omits the passages that I italicised, and to which I took exception. These passages are, in their original, as follows:—"Die Photographie mit Magnesiumpulver in Form von 'Blitzlicht,' wie man es dann nannte, gelangte erst durch die

Arbeiten J. Gaedickes und A. Miethes in Berlin, 1887, zum Aufschwunge (s.u.) und bald beschäftigte sich alle Welt damit, etc.." and "Nachdem Gaedicke und Miethe den neuerlichen Anstoss zur Magnesium-Blitzlichtphotographie gegeben hatte, etc." I consider that the expression, to quote your correspondent's own version, see p. 559, "was first brought to a successful issue," and the statement that Gaedicke and Miethe had given the new impetus to this work as historically erroneous. Dr. Eder now admits that the reduction in price and the gelatine plate may have played some part in the more general use of flashlight.

I did not state that your correspondent called this "epochmachenden." This was quiet sarcasm on my part, and the word was put in inverted commas because it was a foreign word, and because it is a favourite gambit of so many German writers—when recording so-called German discoveries.

The subject is closed as far as I am concerned.—Yours faithfully,

E. J. WALL.

Wollaston, Mass.

NEGATIVES AND ENLARGING COSTS.

To the Editors.

Gentlemen.—The interesting letter from Messrs. Raines and Co., Ltd., in your issue of October 14, raises two points which must be of interest to the many firms who undertake to make prints from negatives developed by other photographers. They are:—

(a) Whether it is possible to get fairly uniform negatives by developing batches of plates by time and temperature.

(b) How many grades of printing paper there really are upon which prints can be made by artificial light out of all the numerous makes and varieties of one make upon the market?

In order to obtain a number of negatives suitable for printing on the *same* printing paper by development to some chosen time, according to the temperature, etc., it is necessary that—

(1) All the plates should be of the same make and batch.

(2) The subjects taken should all present the same total range of light-intensities.

Development by time and temperature together with the fulfilment of condition (1) is what Messrs. Raines wish to obtain in order that they shall be able to reduce the stock of their papers. The subject proviso, however, is equally necessary, and cannot be fulfilled. The range of light-intensities presented by various subjects varies a great deal, and in the same subject it varies according to the lighting. From a flatly-lighted open landscape to a sunlit scene with ordinary transverse shadows in the foreground is a step from a range of brightnesses of about 1—3 in the former to 1—30 in the latter. Similar plates exposed on these subjects would produce, when developed together for the same time, negatives whose printing ranges differed from one another in precisely the same degree as the subject ranges differed. The negative exposed on the 1—3 subject would, if developed for a normal chosen time, require, may be, a vigorous gaslight paper to render a presentable print, whereas the negative exposed upon the 1—30 subject, and developed for the same time, would then require a bromide paper to yield an equally appropriate print. It is usually necessary to exaggerate the range of light-intensities (contrast) in flat subjects, and occasionally necessary to diminish the range of light-intensities (contrast) in subjects of high contrast, in order that harmonious prints may be obtained on similar printing papers, and the only way to do it is to develop each negative for its own appropriate time. Such a procedure is the very antithesis of the "development of a batch of plates for the same time," no matter with what care and accuracy the time according to the temperature be chosen. My own negatives, made on holiday this year, are a striking example of variation in printing quality occasioned by variations in the subject. Those negatives were all made upon plates of the same make and batch. They were developed for the same time under conditions in my dark room which, I venture to hazard, are more accurate than one would usually find prevailing in the workrooms of firms who develop plates on a commercial scale, yet those negatives would break the hearts of Messrs. Raines's printers. They vary in their printing range from 1—10 to 1—60, and they present every conceivable range in between. Their printing requirements have been more or less met by the use of printing papers from vigorous gaslight to "soft" bromide paper, with the occasional use of a "condenser" enlarging lantern to give more contrast to the most feeble of them. It is quite certain that negatives of even printing quality cannot be turned out unless the photographer knows:—

(a) The range of the subject,

(b) The exposure range of the printing paper,

(c) The time of development of the plate which will exactly correlate (a) and (b).

Condition (c) varies nearly every time we expose a plate on a subject, and none of us have more than a very vague idea what that time should be.

The second point, namely, how many grades of gaslight paper and bromide paper there are presenting real differences in printing properties, is worthy of discussion, and is certainly of importance to commercial photographers. Personally, I have never been able to find more than about four, viz., a paper whose exposure range is about 1—10, usually labelled vigorous gaslight paper; another whose exposure range is 1—20, called usually soft or normal gaslight paper; a third, with an exposure range of about 1—35, usually a slow bromide paper; and a fourth, whose range is about 1—50, usually a fast bromide paper. There are several paper makers who can supply these four types, but there are others who do not supply more than two of them, or possibly three. Advertisements, however, read to the contrary, and the reason for the continued faith of photographers in the multiplicity of papers deserves attention. I have on several occasions bought three samples of Messrs. Blank's bromide paper labelled so as to indicate that one packet contained paper giving soft contrast, another paper giving hard contrast, and the third giving contrast of intermediate degree. On each occasion that I have tested them they have yielded identical prints from the same negative. It must be remembered, however, that in testing them they were given equivalent exposures and equivalent degrees of development, a precaution which most photographers overlook. When the exposure and development properties of these papers are worked out, it is found that the "contrasty" paper is *slow* in exposure and very *quick* in development. The "soft" paper is *quick* in exposure and *slow* in development, the very reverse. The tendency is to under-expose and over-develop the "contrasty" paper, and to over-expose and under-develop the "soft" paper. It would be equally efficacious to buy one packet of paper only, and *deliberately* over-expose and under-develop, if one wishes, or *vice versa*. But when normal treatment is given to each paper, namely, equivalent exposures and equal degrees of development, the resultant print differences simply disappear. And it is to be feared that there are a great number of printing papers in existence whose sole differences are their speed and the rapidity with which they develop, and whose gradation qualities (exposure ranges) are identical.

In the present stage of manufacture of gaslight and bromide paper emulsions it is doubtful whether Messrs. Raines can gain anything by stocking more than these four emulsions with real differences. The number of papers will, however, have to be increased where it is desired to possess choice of colour in the paper base and choice of variety in surface. These two features, however, have comparatively little to do with the type of printing negative.—Yours faithfully,

B. T. J. GLOVER.

Sunnymere, Birkenhead Road, Meols, Cheshire.

October 17.

COMMERCIAL V. ARTISTIC PHOTOGRAPHY.

To the Editors.

Gentlemen.—Mr. Wilson, it would seem, has greatly offended the *amour propre* of a section of the high-brows of photographic art, and indeed it is amusing to notice the lofty manner with which they have endeavoured to point out to him that he is really to be pitied in his bewildered ignorance of what constitutes "art" in photography, albeit they have written lengthy letters which do not sound half so convincing as does Mr. Hughes's short but interesting communication that precedes them in to-day's issue of your valued journal.

In Mr. Hughes's letter I find some sort of dismal consolation in that my own abortive attempts gently to persuade the public to

except something more than a mere photograph have had exactly the same results in an entirely different locality. I have for some time past followed precisely the same lines as Mr. Hughes, in so far as submitting extra specimens in which I have flattered myself was displayed a certain amount of "art."

I am quite prepared to receive retorts that evidently mine is not true art, but at the same time I am convinced that a vast majority of the public do not and will not take kindly to the portraiture (so-called) that is perpertrated by many "camera artists."

It is admittedly a good thing to strive to turn out artistic photographs, but the superimposing of a systematic arrangement of fly-blows on otherwise useful portraits (as was to be seen at the London Salon of Photography) and much-faked shadowgraphs will not help the photographer who endeavours to earn some sort of living by his profession, and, more important still, does not happen to live in an ultra-modern district.—Yours faithfully,

Duke Street, Chelmsford. October 14. G. A. SMITH.

To the Editors.

Gentlemen,—I have been interested in the correspondence relating to an article by Mr. Godfrey Wilson, in which the medal pictures of Mr. R. H. Lord, of Cambridge, are mentioned. As I was 20 years with the photographer mentioned and printed all the pictures exhibited and for which he won about 30 medals, I am in a position to know the commercial value of the same to Mr. Lord. I should be within the mark if I state I have printed *hundreds* as ordered and numbers have been sent all over the world right up to the last two years or so, when, unfortunately, the negatives were destroyed by flood in a terrible thunder-storm. Orders have reached me since then. Good prices were obtained for the copies and the total amount paid in those years must have been considerable.

Apart from their artistic merits, they were a valuable advertisement, as he was careful to let people know they were *not enlargements* executed by a trade enlarger, but *taken direct* on 20 x 22-inch plates with a camera of that size. That scored considerably and greatly enhanced his reputation as an artist and photographer.

I had all the negatives till they were destroyed, and have the camera and Voigtlander Euryscope with which all Mr. Lord's medal pictures were taken still in my possession.

It may interest many of Mr. Lord's friends to know he has made a considerable fortune and is living retired near Manchester.—Yours faithfully,

E. A. BASEVI.

48, New Road, Chippenham, Wilts. October 16.

REVERSAL IN DEVELOPMENT.

To the Editors.

Gentlemen,—Referring to Mr. Cooper's letter and illustration *re* the freak half-negative and half-positive photograph published on page 319 of the "B.J." for May 27, 1921, I enclose print of a studio photograph showing a similar result to that of Mr. Cooper's, which may interest you. This "negative," however, was developed with a batch in the ordinary way, but was not exposed to the slightest white light during development; the other negatives of the same person were perfectly correct.—Yours faithfully,

7, Easy Row, Birmingham, October 15. J. HALSON.

[The negative print sent by our correspondent is evidently made from a positive of quite ordinary character.—EDS. "B. J."]

PAPER FOR ALBUMENISING.

To the Editors.

Gentlemen,—Referring to your "Answers to Correspondents," R. B., in your issue of October 7 *re* albumenised papers, I beg to say that albumenising paper has always been a specialty and, as a fact, a monopoly of the Papeteries de Rives and Messrs. Steinbach & Co., of Malmedy, Belgium. The General Paper Company of Brussels, whom I represent in this country, has the sole sale of the photographic papers of these two mills, and albumenising papers can be obtained from them.—Yours faithfully, F. C. MILLER.

PLATES *V.* FILMS.

To the Editors.

Gentlemen,—With reference to the above controversy, there is absolutely nothing in it. With a plate it is possible to get as good a result as with a film; back the plate and you can even get those bold and unusual things in lightings. The backing is not objectionable; it washes off during development.

Mr. Mattison states in his letter that films make better negatives than plates ever made or can make.

I should like to know how he arrived at this decision. Is it by results produced with his own hands, or from what have been shown to him?

Anyhow, my answer to that statement is, that until quite recently I have produced better negatives on Royal Standard Lightning Plates than on films, and since the Kodak Co. have ceased to make plates I have found another plate capable of producing the same results.

Therefore if the Kodak Co. care to send and take some portraits on their films in my studio I will at the same time take and produce an equally good negative on a plate.—Yours faithfully.

ALEXANDER CORBETT.

48, Baker Street, Portman Square, London, W.1. October 18.

To the Editors.

Gentlemen,—The last word of this discussion can surely remain neither with Messrs. Kodak nor with the experienced photographers who have expressed their views in your correspondence columns at length and with singular absence of unanimity. Having neither an adequate amount of knowledge nor experience, I do not presume to enter the controversy, but as an amateur modestly interested in the scientific aspects of photographic processes I have read Messrs. Kodak's letter of the 11th inst. with much disappointment, although it bears the name of Mr. Mattison, the managing director.

Apart from the concluding paragraph of their letter, in which Messrs. Kodak announce a concession to critics of the speed of their film, the whole communication would, I submit, find a more suitable place in your advertisement columns as an *ex parte* statement and a choice example of that form of bold assertion which is found by many advertisers so usefully to produce the effects which they desire.

Messrs. Kodak are believed to have an unrivalled staff of photographic scientists. Would not the firm's assertions carry greater conviction if they were supported by a paper from the Kodak Research Laboratory? Or is there no eminent English worker who would make accurate comparative tests and place this highly interesting and important question beyond discussion by the issue of a comprehensive account of his results?

Given a truly non-halative, truly flat film, having adequate speed and fine grain, sensitive to the whole of the visible spectrum, and non-inflammable, few photographers would, I think, hesitate to use such a perfect material. Messrs. Kodak, however, do not appear to claim that their potrait film is either panchromatic or non-inflammable. Personally, I would sacrifice the latter condition for the sake of the former, but this view differs from the question of the non-halativeness of film in being a matter of individual preference rather than a disputed point of importance which can be settled satisfactorily only by exact, authoritative and impartial tests.—Yours faithfully.

H. JERVIS, M.A.

—Carisbrooke, Isle of Wight. October 17.

[This discussion, having now been continued for seven weeks, is closed for the present.—EDS. "B. J."]

ILLUMINANTS FOR ENLARGING: PLATES FOR SMALL CAMERAS.

To the Editors.

Gentlemen,—In his letter on p. 619 of your current issue "Old Hand" refers to the inability of some lenses to work to focus in an enlarger with electric light, arc or incandescent. I have an anastigmat of exquisite quality that fails with incandescent gas. I cannot recollect having seen any mention of this possibility anywhere except in the editorial article on enlarging in the "B.J. Almanac" for 1915, p. 379.

The somewhat pronounced grain of films may explain why most miniature cameras are built for plates. None of the special fine-grain emulsions seem, however, to be coated on extra thin glass in the miniature sizes. There is, furthermore, no such plate in the "Non-Screen" series, either normal or miniature.

Telephotography is based on coarse grain. If one could expose at *f*/6 and enlarge 8 diameters without breaking up the image, it would be simpler—in most cases—than taking a telephotograph at *f*/48.—Yours faithfully, "MAGNIFIER."

October 18.

Answers to Correspondents.

In accordance with our present practice a relatively small space is allotted in each issue to replies to correspondents.

We will answer by post if stamped and addressed envelope is enclosed for reply, 5-cent International Coupon, from readers abroad.

Queries to be answered in the Friday's "Journal" must reach us not later than Tuesday (posted Monday), and should be addressed to the Editors.

PELMAN.—The firm to which you refer is Messrs. Ventiheta, Ltd., of Argyle Street, Oxford Circus, London, W.

S. B.—If the photograph was taken in the ordinary way, that is to say, not by invitation of the photographer, the sitter has complete rights in the portrait, and at her wish you are perfectly entitled to make any copies.

C. WHITE.—If we understand your question correctly, you wish to re-sensitize old negatives. There is no means of doing this except by completely cleaning off the gelatine coating and re-coating with emulsion.

LANTERNIST. —Oil-colours suitable for the colouring of lantern-slides may be obtained from Messrs. Winsor & Newton, Ltd., 37-40, Rathbone Place, Oxford Street, London, W.1, or through any dealer in artists' materials.

C. M.—Rights to photograph on the beaches of seaside resorts are almost always administered by the local authorities concerned, Town Councils or Urban or Rural District Councils. Very frequently they are offered to tender. You should apply to the Clerk to the district council in the places in which you are interested.

T S.—We have indicated size and position of glass on your diagram. You can, if you please, have more glass, but as the room is also to be used for another purpose too much glass will cause it to be cold in the winter. Ordinary strong horticultural glass will answer perfectly. The 6-ft. fence will not materially interfere with the light; it would, however, be as well to whiten it.

N E.—All we can say is that there have been a number of instances of commercial travellers for the photographic manufacturing and wholesale firms having been recruited from professional photographers of experience. The rule however, is for travellers to be drawn from the lower ranks of employees in a firm, such as salesmen and other assistants. There is no special journal used by the wholesalers.

E. M.—We do not know that there is any definite remedy for skin poisoning caused by hydrochloric acid. The best recommendation which we can make is that the skin be kept soft by regular use of an emollient paste, such as Lanoline cream. Also, the fingers should be well rinsed in tepid water every time after they have come in contact with the acid.

S. C.—(1) On the whole, we think the gas lamp is the best, at any rate if the studio is of ample size and well ventilated. If otherwise, the heat of a gas installation is liable to become excessive if much in use, and particularly during the warmer part of the year. (2) As a rule about 20 mantles, preferably of the Howellite inverted pattern. (3) If you allow 4 ft. for the space behind the sitter and behind the camera you can use a 7½-inch lens for cabinet full lengths and c. de v. half-lengths. In an 18 ft. run of studio you would require a shorter focus lens for c. de v. full lengths.

C. E.—As the London photographer appears to be exhibiting the portrait by way of trade, that in itself is an infringement of your copyright in the portrait, and if you like you can take action to make him withdraw it from exhibition. Apart from that, the act of passing off your work as his is a civil offence, in respect to which, we think, you have a perfect legal remedy. If the photographer is not immediately disposed to do what you require, we should think that a letter from your solicitor would speedily have the required result.

H. W.—The best book is "Photography in Colours," by Dr. Lindsay Johnson. Our own publishers supply this, price 6s. 6d., post free, or you could obtain it through any bookseller. But actually the processes available at the present time for three-colour photography are very few in number. Apart from the Paget and Autochrome processes, the only one for which the materials are commercially available is the Raydex of the Raydex Co., 71, Lavender Hill, London, S.W.11. The instruction booklet of this firm deals very fully with the process.

W. B.—You will require from 12 to 18 burners, and we do not believe you can do better than to arrange them upon a portable stand similar to that used for the Kodak "Powerful" gas lamp. It is necessary to have a white reflector behind the burners, but if these are not placed too close together you will not require any diffuser. If you could get a powerful lamp and change the burners it would save you a lot of trouble. Be sure to keep the studio well ventilated, as a large number of acetylene burners in a small space will rapidly vitiate the atmosphere and cause headache.

J. BLICH.—The choice of gas installations for studio portraiture is limited. At the present time the only equipment on the market is the Howellite, supplied by Messrs. Griffins, Kemble Street, Kingsway, London, W.C.2. This is a very good outfit of about twenty inverted incandescent burners, and is quite effective for single portraits, and, at a pinch, for small groups. But you require to consider that twenty such burners give out a good deal of heat, and in such a small space as you have available the heat at times might easily be uncomfortable. In any event, you would require to provide ample ventilation.

L. J.—We do not know the composition "Claricit," but it evidently acts by producing a slight, greasy film upon the glass. A method which was long kept a secret by professional window-cleaners is to rub a little glycerine over the window, and then to polish off as thoroughly as possible. Ordinary petroleum is said to have somewhat the same effect. We should not recommend putting anything upon the surfaces of lenses. These may be cleaned with a drop or two of pure alcohol. When not in use, they should be protected with front and back caps, and in the winter should be kept during the night in a warm, dry place. Nothing can be done to prevent windows becoming dull in foggy weather, as the dullness is due to the deposition of soot and tarry matters from the smoke, but steaming is preventable by using glycerine.

JOURNAL OF PHOTOGRAPHY.

No. 3208. Vol. LXVIII. FRIDAY, OCTOBER 28, 1921. Price Fourpence.

Contents.

SUMMARY.

In a contributed article Mr Henry J. Comley maintains the importance of individual style in present-day portrait photography. (P. 640.)

An article by the late C. Brangwin-Barnes, and conceived in a spirit of imaginative forecast, will be found on page 643.

Dr. H. D'Arcy Power, in a recent issue of his journal, "Camera Craft," examines the form of optical reproduction which is most closely in accordance with natural vision, and expresses his preference for that produced by lenses giving a certain degree of diffused focus. He gives particulars of the properties of the commercial quartz lenses introduced as the result of his own experiments. (P. 641.)

In a leading article we refer to the Safeguarding of Industries Act in its present relation to the sale of ex-enemy goods. (P. 638.)

In a brief communication from the Eastman Research Laboratory, Mr. E. R. Bullock discusses the behaviour in a developer of the faintly alkaline substances, such as borax and bicarbonate, which are occasionally employed as restrainers. (P. 639.)

A correspondent of "Abel's Weekly" gives formulæ for the preparation of a hypo-alum-gold toning bath, which has been found to be exceedingly reliable and satisfactory in use. (P. 650.)

At the Royal Photographic Society on Tuesday evening last two papers dealt with different aspects of the silver-bromide grain of emulsions, and another with a roller method of more uniform development. (P. 648.)

A labour-saving device for getting rid of litter on the dark-room floor is the subject of a paragraph on page 637.

Repeated intensification of a negative or print by means of the Carbro process is a method for rendering visible faint impressions in copies of documents such as those which have been severely damaged by fire. (P. 638.)

The Mannl process for the contact copying of originals by the light selectively reflected from different parts of them is described in "Photo-Mechanical Notes." (P. 645.)

A contributor to "Assistants' Notes" gives a table of factors for the use of the B J pyro-soda formula. (P. 645.)

The exhibition of the Royal Photographic Society closes to-morrow, Saturday, October 29.

Full re-development is a precaution in the use of the chromium intensifier which is sometimes overlooked. (P. 638.)

A note on the rare defect of small red markings on bromide paper will be found on page 637.

Repair of studio roofs, efficiency of the focal-plane shutter, copyright in a portrait, and defects in negatives and prints are the subjects of brief replies to correspondents. (P. 651.)

A profuse symbolism is employed by a German patentee of systems of producing silhouette photographs. (P. 647.)

EX CATHEDRA.

The Dark-Room Floor. Recently, in the dark-room of a commercial photographer friend of ours, who prides himself on his labour-saving devices, we noticed an arrangement which does a great deal towards keeping the dark-room floor free from litter at the minimum expenditure of labour. An assistant was sweeping up the floor of the room, and we expected to see him stoop to gather together the accumulation of plate wrappings, separators, and other paper refuse which in many dark-rooms is scattered on the floor. Instead, he opened the door of a small cupboard on the floor level in the corner of the room, and there, inside, was a hole in the floor about 8 or 9 inches in diameter, into which the collection of rubbish was quickly delivered with a stroke or two of the broom. A visit to the basement showed that a piece of wide stove piping was connected to the hole, and immediately below it a sack was placed for the collection of the paper refuse. There are, no doubt, many dark-rooms, such as those situated in basements or immediately above rooms required for more ornamental purposes, to which this arrangement cannot be applied; but in those in which it is possible the plan is plainly a most effective one for keeping the floor of the room in a neat and tidy condition.

* * *

Red Marks on Bromide Paper In a long and daily experience of dealing with defects in prints and negatives sent to us by our readers, it is very seldom that we have to come to the conclusion that the cause of the defect is a fault in manufacture. The standard maintained in the examination of their products by makers of plates and papers is an extraordinarily high one, and users are no more than discreet if they exhaust every possibility of error or accident in manipulation before they attribute defects to faults in manufacture. When, however, the latter appears to be the only explanation, it is also our experience that manufacturers, obviously in their own interests, are most ready to investigate the case. We had an instance of this the other day, when a correspondent sent us a batch of bromide prints bearing minute markings in the shape of short almost straight lines of a bright red colour. We could find no explanation of the defect and advised reference to the makers. Our correspondent has since informed us that the makers immediately identified the markings as due to a fault in the preparation of the raw base, namely, the escape of the colouring matter on to the paper. In immediately admitting a fault which should have been noticed by the examiners and the material thrown out, they expressed their readiness to replace the defective material. Since we have advised the reference of these exceptional cases to the makers, we must also urge the further recommendation that the fullest particulars of developer, fixer, and mechanical manipulation of washing and drying should be stated in making any inquiry. We have our

own experiences of the futilely vague questions which are addressed to us, and we daresay the makers have theirs.

* * *

Intensifying Faint Impressions. In a recent article in the French technological journal "Génie Civil" appears a review of the photographic methods employed in deciphering faint impressions in documents, such as faded manuscripts or the charred remains of papers which have been burnt but have afterwards been pieced together. In this branch of work it is an old method to copy and re-copy several times, on plates giving a high degree of contrast, the faint impression in the original document. According to a French technical worker, M. Faworski, a more rapid and certain method of carrying out this principle is by means of a form of the Ozobrome process, or Carbro as it is now termed. The gelatine-pigment tissue, soaked in the mixture of bichromate, ferricyanide and other salts, is applied to the negative first developed. After twenty or thirty minutes' contact, development is done in warm water and the paper support of the tissue stripped off. The original image is thus intensified by the addition of pigment, and is itself left in the form of silver ferrocyanide. It is reduced again to the metallic state by any developer, and this process may be repeated as many times as is necessary, employing a fresh sheet of carbon tissue for each operation. From the negative so obtained a print is made on bromide paper which, again, may be intensified in like manner, if the extreme faintness of the original impression renders this procedure necessary.

* * *

Clerical Portraits. The average portrait photographer is often somewhat at a loss with clerical sitters, and the portrait generally resolves itself into the usual thing, the sitter in a pulpit attitude, hand on book, and generally with a strained expression. For no matter how much at home the parish priest may be in his pulpit, he is inclined to feel rather uncomfortable when posed accordingly for his photograph. The cassock may often be pressed into service to lend a note of character to the picture, and while the idea is often carried out successfully, it need not exhaust the possibilities of successful portraiture of the more popular among the clergy. We see no reason why the surplice and stole should not be employed more for clerical portraiture, and even the altar vestments. Such pictures appeal not only to the cleric himself, but also to the wider circle among his friends and parishioners. One word of caution may be added. If the portrait is to be made with the priest attired in richly-coloured vestments, it is most important to use a colour-sensitive plate, since a proper colour rendering is most desirable. If permission can be obtained, it is possible that good business may be done by the issue of postcards from negatives taken as suggested. There is also a possibility that the idea may be extended to choirmen, servers, crucifers, thurifers, and other officials of the Church attired for their various offices.

* * *

Chromium Intensifier. Those photographers who use the popular chromium intensifier, and who have not had results as good as anticipated from descriptions, verbal or written, as to what this process is capable of producing, should ask themselves if they have given the negative long enough in the developer. If the process is carefully watched it will be seen that re-development is fairly rapid up to a certain point, when the action seems to stop. Many workers that we have known have taken the negative out of the developer at this stage, under the impression that the maximum effect of the intensifier had been reached. In order to obtain the fullest advantage of the process the worker should leave the plate in the developer for a much longer period than is customary. It will be noticed that density is gained quite slowly, but the effect of the intensification is greatly enhanced; in fact, no harm will result if the plate is left in a non-staining developer for twenty minutes or half an hour. One of the advantages of this method of intensification is that the process is completely under control, and little or much density may be added to the original image, either by partial bleaching or by the removal of the negative from the re-developing solution before its fullest density is obtained. Many workers do not allow enough light to fall upon the plate while this is being done.

THE ACT AND EX-ENEMY GOODS.

The Safeguarding of Industries Act, which came into operation at the beginning of the present month, does not seem so far to have aroused any great degree of enthusiasm among manufacturers or merchants who are affected by it. In the trade journals of the industries to which it chiefly applies, namely, those of optical instruments and chemicals, little cordial confirmation of its value has appeared. The chief signs of such sentiment which we have noticed are one or two announcements of reduction of prices of goods by British producers, made, as is said, in anticipation of increased demand. But in these cases it may be seriously questioned if reductions have been made possible by the Act; the recent further fall in the value of the mark may perhaps have been a not negligible determining fact. For it can hardly be supposed that the 33⅓ per cent. duty imposed by the Act on goods imported from whatever country to which the Act applies is an adequate measure of protection against competition by makers in countries where the currency is so depreciated as in the States of the former Central Empires. It may be, and apparently is, effective in respect to France and Italy, but very partially so as regards the chief source of lower-priced goods. But in this respect the Act is inelastic, taking no account of the degrees of depreciation of the currencies of foreign countries, but taxing the goods of all alike. In another respect, however, the Act has already shown itself elastic in a manner which was not generally anticipated. Designed ostensibly, as its title conveys, for the protection of industries in this country, it has already been found to be taxing goods, *e.g.*, certain chemicals, which are not made and never have been made in this country; and, generally speaking, the criticism of it in the chemical journals is that in its administration the distinction between the "fine" and "heavy" chemical trade has been lost in great measure, and that the tax has been applied to chemicals used and sold in bulk, which it was not anticipated would come within its scope. Even in the photographic trade we have an instance of the same wandering of the Act from its alleged purpose of safeguarding industries here. Cameras are included within its scope as "optical instruments," and are taxed without relation to their very various types, some of which have never been made here. It may, perhaps, be argued that the taxation of all-metal 45 x 107 mm. stereoscopic cameras, a specialty of several French makers, is a safeguard for our own camera industry; but, if so, it is one of microscopical proportions. We do not believe that the tax on them will foster the manufacture of those cameras here or, alternatively, enhance the sales of cameras of the kinds made here. On the other hand,

its imposition invites retaliation abroad in the shape of a tariff on British goods in foreign markets, as is reported to have been raised by Portugal, or a commercial treaty with Germany, such as was carried out by Italy some time ago with serious results to the market in British goods in the latter country. It may well be that a tariff which gives protection in the home market is a doubtful benefit if it reacts to our disadvantage in markets overseas. Manufacturers most immediately concerned with German competition are no doubt thankful for the Act to the extent of getting at least some slight protection, and no doubt equally realise its inadequacy as a remedy of the low-level fluctuations of the German exchange.

That the Act is in fact an ineffective instrument in the conditions at present prevailing between this country and Germany is evident from the small notice that is taken of it by advocates of a boycott of ex-enemy goods. It is now recognised that it does not provide the means for keeping out ex-enemy goods, and hence stress is laid on the sentimental objections to dealing in them. Much as we hold in abhorrence the war methods of our late enemies, we cannot put on one side the almost daily observation that such considerations have little weight in commercial dealings, large or small. As a journal which, for the three years since the Armistice which are on the point of being completed, has consistently refused advertisements of ex-enemy goods, we have had perhaps more than the average volume of evidence in justification of that view. There will, undoubtedly, always be people who will not knowingly buy ex-enemy goods at any advantage of price. But unless we are much mistaken, they are few in comparison with those to whom price or, less frequently, the precise fulfilment of their requirements is the sole consideration. Moreover, almost daily experience has shown us the great difficulties of effectively excluding the announcements of ex-enemy goods. There are, for example, at the present time firms handling both British and ex-enemy goods who advertise only the former, but whose advertisements are, nevertheless, largely designed to bring inquiries for the latter. Yet we believe it would be unanimously thought to be contrary to the English spirit to exclude them on that account. Again, apparatus represented as "second-hand" cannot be reasonably objected to. It is plainly impossible for a newspaper to investigate; while it may observe a remarkable number of advertisements of ex-enemy goods for sale "in new condition," the rejection of all and sundry of that kind would obviously inflict inconvenience on many people. These instances are cited for the purpose of drawing attention to what for some time past has been an equivocal position for any journal which rejects, or rather does its utmost to reject, advertisements of ex-enemy goods. It was hoped that the Safeguarding of Industries Act or the success of manufacturers, or both together, would substantially remedy this state of affairs, but these measures unfortunately stand little chance of making their influence felt in the present prevailing international economic conditions; and it thus appears that the efforts of newspapers to exclude ex-enemy products from their pages, while largely successful up to a point, have invited methods of camouflage which actually are more objectionable than a downright undisguised offering of such goods. In the latter event, the public would know where it stands; and it seems that the time has arrived when a discussion of the relation of class newspapers to their readers on the one hand and to manufacturers and dealers on the other would be of benefit in exhibiting the balance of opinion on the subject.

RESTRAINT OF DEVELOPMENT BY BORAX, Etc.

(A communication by the Eastman Research Laboratory to the "Photographic Journal of America.")

It has long been known that the addition of borax, sodium bicarbonate, or ordinary sodium phosphate to a developer produces, under certain circumstances, an apparent restraint of development. The effect is especially pronounced when the developer is one containing an organic developing agent of relatively low reduction potential (such as hydroquinone or pyrogallol), a caustic alkali (soda or potash), and considerable bromide. Luppo-Cramer has dealt with the subject in several papers which appeared in "Photographische Korrespondenz" in 1915; and the greater number of the experiments there described have been repeated by the writer on lantern plates, in connection with the sepia toning of these by direct development. The results obtained confirmed those secured previously by Luppo-Cramer. Luppo-Cramer explained the restraining effect produced by the addition of borax and similar salts to the developer as being due to the low solubility of the silver salts corresponding to the substances in question which influences the amount of free silver in solution. He has pointed out further that sulphates, acetates, and tartrates do not give the effect, the solubility of the corresponding silver salts being too considerable. And an experiment which he made with sodium salicylate (as an example of a salt of an acid whose silver salt is only difficultly soluble) showed that this salt gives typically the borax effect. A study of the various silver salts of low solubility arranged in order of insolubility shows, however, that there are great anomalies in the actions of oxalates and succinates, which do not give the borax effect, and fall between the carbonates and salicylates, which do give it. Moreover, it is difficult to explain how any salt like borax or sodium phosphate, where the supposed corresponding silver salt has a solubility many times greater than that of silver bromide or even silver chloride, can have any detectable restraining action of the same nature as that exerted by an ordinary soluble bromide. There are, indeed, restrainers of the bromide type, those of practical importance being potassium iodide and potassium bromide for silver brom-iodide and silver bromide emulsions, and potassium iodide, potassium bromide, potassium ferrocyanide and sodium chloride for silver chlor-bromide and silver chloride emulsions, and it is usual to restrict the name "restrainer" to such salts as these.

But the velocity of ordinary photographic development is not dependent only on the maximum concentration of silver which is possible in the developer. It is dependent also on the alkalinity; and in regard to the alkalinity of solutions, the actual facts are not always exactly as might be supposed. It might be supposed that a substance which is alkaline when dissolved in pure water will, when dissolved in a solution which is already alkaline, increase the alkalinity of the latter. An example will show, however, that as regards the active alkalinity, this is not invariably the case. Both caustic soda and sodium bicarbonate are alkaline. Caustic soda is very alkaline. Sodium bicarbonate, on the other hand, is only very slightly alkaline. If, however, the caustic soda and the sodium bicarbonate are both dissolved in the water, or if the caustic soda is dissolved in the sodium bicarbonate, or *vice versâ*, the alkalinity of the solution is identical with that of a corresponding sodium carbonate solution and is very much

less alkaline than the caustic soda itself. In other words, a neutralisation of about nine-tenths of the active alkalinity of the caustic soda solution has been brought about by the addition of a substance which itself gives a feebly alkaline solution when dissolved alone in pure water. It is very obvious that the result of an addition of sodium bicarbonate to a developer which has been made up with caustic soda is a reduction in alkalinity, and consequently a restraining action. And a similar explanation is applicable to borax and to each of the other salts which show the borax effect; for in every case the salt added is the potentially acid salt of a somewhat feebly dissociated acid and, while itself alkaline in reaction, nevertheless forms with caustic soda a normal salt the alkalinity of which is very much less than the mean of the respective alkalinities of the original salt and caustic soda. In the case of borax itself we have a potentially acid salt of a weak acid, for the ortho acid of boron containing two atoms of boron in its molecule has the composition $(OH)_2$-B-O-B-$(OH)_2$, or empirically $H_4B_2O_5$, and the equation

$$Na_2B_4O_7 + 6NaOH = 2Na_4B_2O_5 + 3H_2O$$

expresses the formation of its normal sodium salt.

Sodium salicylate, $C_6H_4(OH)(COONa)$, can be considered an acid salt, inasmuch as it still contains replaceable hydrogen and the reaction with caustic soda,

$$C_6H_4(OH)(COONa) + NaOH = C_6H_4(ONa)(COONa) + H_2O$$

takes place to a certain extent.

From the foregoing remarks, it will be gathered that alkalinity is composite in nature. While it is only the active alkalinity (hydroxyl-ion concentration) which counts when the speed of development at any given moment is considered, the other component, which is called the reserve alkalinity, is of some importance as determining the resistance of the developer to diminution of its active alkalinity with use. Without entering into the theory of this effect, it may be simply stated that, if the active alkalinity and other conditions are the same, the greater the reserve alkalinity of a developer the more uniform its action may be expected to be and the longer its useful life. In ordinary photographic practice, indeed, the alkali most commonly used is sodium carbonate, which already possesses considerable reserve alkalinity, and caustic soda or potash (with scarcely any reserve alkalinity) is ordinarily used only when speed is of importance.

Conclusions.

1. The borax effect—the retardation of the speed of development under certain conditions, shown by borax and certain other sodium salts—cannot in any degree be attributed, as has been suggested by Lüppo-Cramer, to the low solubility of the corresponding silver salts.

2. The borax effect is due to the diminution of the active alkalinity of a developing solution which occurs in consequence of a chemical reaction between the borax or similar salt and the alkali already present in the solution.

E. R. Bullock.

INDIVIDUALITY IN PROFESSIONAL PORTRAITURE

In a long and varied experience it has been the writer's privilege to meet with a large number of photographers of extremely divergent capacity both for business and for artistic attainment. In many cases a casual acquaintanceship has developed into a lasting and much-prized friendship. I have visited them in their studios, seen their work and the work of other photographers in their vicinity, and have had the opportunity for comparison and friendly criticism which has often been appreciated. But one has frequently been impressed by the unambitious, commonplace level which characterises so much of this work, and above which it fails to rise. So that one is led to seek for some definite reason why so many professional photographers—good fellows all—seem to be unable to get out of the rut of mediocrity; and, further, to discover, on the other hand, why some of them do succeed in doing so; raising the level of their regular studio work so that it stands conspicuously apart, possessing a character and quality which commands attention, claiming for itself a position in the world of photographic portraiture which is unassailable and from which we could not supplant it even if we had the trepidity to attempt to do so.

But these men would be among the last to claim any superior qualifications over those of their less successful brethren. Ask them the reason why their work possesses that subtle "something" which makes it distinctive. They cannot tell you! They only wonder why other photographers do not produce work of a similar character; and their reply may be in the nature of a question as to your own reason for not doing so. Yet there is a factor which is in a large measure responsible for this "something which is different," and I believe it is a factor which is unconsciously possessed by every one of us. It is the ability, not only to live by our work, but to live in it.

To give to it something of ourselves, something which would make it worth the doing, and impart to it the distinctiveness of our own personality. In other words, to put into it something which is akin to life itself, namely, "Individuality." Undoubtedly we are all—more or less—influenced by the work and mode of thought of other people. We observe this in the influence which the study of mediæval art and the work of modern masters impresses itself upon the work of the younger generation of artists, sculptors, and designers; sometimes leading them in a quest for an ideal upon which to build their own reputation. We have seen the same spirits of the past and the present uniting their efforts in the development of modern photography, and in the artistic evolution of some of our contemporary workers before they have settled down into serious endeavour and eventually given us original conceptions which have lifted their work out of the commonplace and by its individuality compelled appreciative recognition.

We know of more than one man who, after many years of plodding along in the smaller lifeless kind of work, has suddenly burst away from it, and in a comparatively short time built up for himself an artistic reputation, and gained an assured position as an illustrious member of the fraternity. Were it permissible to mention names in this connection the reader would recognise them as men who are to-day among our honoured leaders in professional portraiture. It will therefore be clear that some such factor as I suggest really exists and that it is a personal one.

I further submit that the character of a man's work is influenced by his own attitude toward that work, and that apart from the accident of external influences it is generally to this personal attitude that one must look in order to discover a reason for the success or otherwise of any particular enterprise. In an intimate business like photographic portraiture personality is a factor which has a value, a great commercial value; but a personality, however charming or magnetic, cannot long remain a sole reason why customers are attracted to any particular business establishment. The principal attraction to any photographic studio must necessarily be the work which emanates from it, and unless one's attitude toward that work is one of interested sympathy, it is natural to assume that the character of the work will vary with the ability of the assistants to whom the doing of it will have probably been delegated. There are many small—often

very select—country and suburban studios where the whole of the work is personally carried through by the proprietor; it would be reasonable to expect that in this work one would find a pleasing, not to say exceptional, element of individuality, but, unfortunately, this does not often follow. More frequently it will be found that the running of a single-handed business with little opportunity for recreation or rest becomes burdensome and monotonous, and the good intentions and ambitious ideals with which the business may have been started are soon relaxed; and although great pains may be taken to produce clean, acceptable work, it often possesses nothing which would distinguish it or stamp it indelibly as the work of any particular man. In a business possessing a clientele extensive enough to support a really competent assistant or two, far better work will be done, showing considerably more character, and possessing a greater charm of variety, because the production of such work has the interest of more minds than one, and the consensus of such mentality will tend to produce pictures which are characterised by their technical excellence and beauty and which will avoid the monotony of the egoism which is so observable in the work of a few single-handed producers whose efforts have received much laudation at the hands of their friends. I purposely differentiate between "egoism" and "individuality" because the spirit of "egoism" is particularly distasteful to me, while the man whose ideal is a lofty one will always have my sympathy, for while the imprint of his individuality is undoubtedly impressed upon his work, it does not blatantly shout its author's name into one's ear.

Who can look upon really great portrait work without having the realisation that here we have work which is distinctive and different from the common order. The productions of such men contain factors which are not comparable one with the other. They express the individuality of different men. But why should they do so? We know perfectly well that apart from the actual study of the sitter the productions of our foremost men are not personally executed. It must follow therefore that the whole of their business organisation—the studio, the workrooms, the handicraft of their assistants—are all controlled by the same individualism which reflects the mind of the man whose interests and reputation are bound up in them; and in all the stages through which the work passes his personality is apparent

To discuss his personal work in the studio would interest very few. They would see nothing in it which differs from their own practice; but it is not the things which are done but the manner of the doing which matters. The attention to detail, the personal interest, the inherent love for the work which he has in hand which combines to make it distinctive. It is an education to see some of our leading men at work, and having seen them one is able to realise why their work is distinctive. They put more than time and thought into it. They put into it something of themselves, call it "soul" if you wish, but whatever it is there is no doubt that it carries into the work the hall-mark of an individuality which gives to it the distinction compelling our admiration. He never works at haphazard; he is deliberate and decisive. He doesn't expose plate after plate with little or no variation of arrangement, in doubt as to whether this or that or the other will be the most successful result. He knows what he is aiming at, and gets it—barring accidents—every time. To him the exposure of a plate is a matter of import; and his success must be largely attributed to the faculty which he has for taking pains in every action which he performs in the studio; not solely for the satisfaction of his customer, but also for the satisfaction of the consciousness within him which demands the best of which he is capable and can be content with nothing less. It would appear therefore that in order to emulate the characteristic individuality which we have been considering, it is necessary to study closely our personal attitude toward our own work. It would be sheer waste of time to attempt to advise any one to imitate any particular method or mannerism in order to individualise their own work.

To invite success one must be supremely natural and personal. Originality of thought or action can only be acquired by these means. The world contains too many servile imitators of other people's ideas. The professional photographer who wishes to be recognised in his work must *put himself into it*, fashion it with that regard for the dictates of his own nature, which will make it a part of himself He must love the work for the sake of the work itself, and for the pleasure which it affords him when engaged in it. Though it is his life's vocation, he must never cease to be an amateur in the truest sense of the word, or he will utterly fail to rise to the height of his ambition and achieve the distinctive note of individuality by which he may be recognised in his work.

HENRY J. COMLEY.

SOFT-FOCUS LENSES.

[In the following article in "Camera Craft," Dr. D'Arcy Power reviews the oft-discussed difference between the images formed by the eye and by lenses and bestows his approval on the soft-focus lens as the best means of imitating the effect of natural vision in a photograph. While we do not agree that a uniform even though slight subjugation of sharpness is true to nature—and Dr Power in one place admits as much—we find space for his paper on account of its clear treatment of the subject and particularly for its description of the properties of the quartz soft-focus lenses, the introduction of which followed from Dr. Power's experiments.—EDS. "B.J."]

THE evolution of the popularity of the soft-focus lens is not only an example of the improvement in artistic taste, but a return to the normal way of seeing things. When the lens picture first greeted the public it came as a wonder. The photograph recalled everything the child's dimples and grandmother's wrinkles, the stamens in the flower and the spider's web, nay, with the hand glass you might perchance detect the beetle in the bud Here were pictures such as no artist had ever made, or ever could. No wonder we had an enthusiastic world. "True as a photograph" became an axiom, and yet artists did not like photographs; a few, such as Hill, tried the camera for a while, but soon went back to the pencil and paint brush. All kinds of reasons were given; jealousy said some; false values, a lack of selection, confusing distribution of lights, and other faults replied the artists. Things the laity did not understand.

Presently came the hand camera and everybody made photographs, made them with the ambition of getting them sharp and clear, so that they could see everything that they knew was in sight of the camera. With *f*/64 and ferrotyped Solio, they often did. The greater their success, the less use the artist had for the process. Why? Because the lens picture is one that no eye has ever seen.

A good lens sees everything at once and equally well, the human eye at a given time sees only the object to which its attention is directed: all else is dimly apprehended with increasing blurring as the centre of interest is left. The eye may change its position and retain a memory picture of what it just observed, but the object of interest will always dominate the rest because it is most looked at and best remembered. This fact a good artist unconsciously embodies in his picture, but the lens has no preferences, it gives all, and owing to the

small size of photographs the eye cannot exclude the uninteresting from the field of vision. The artist whose training leads him to seek for the true appearance of things, naturally rejects an image he never sees in nature. With the everyday man it is different; his ideas of what things look like is made up of what he knows they are. He is sure that a tree consists of a trunk, branches and leaves, but he does not reflect that he cannot see a tree and every one of the leaves at the same time. If he obtains a photograph that does this very thing (because the small size of both images can come within the focus of the eye) he accepts it, inasmuch as it fulfils his idea of truth. The everyday man is interested in facts; the more facts he finds the greater his appreciation. So he admires the pictures of Claude Lorrain stuffed with figures and architecture, the photograph, that he can examine with a hand glass and find something otherwise invisible.

Many painters in the early days of art were obsessed with the same idea. That is long past; more and more the aim is to give what is actually seen, leaving it to the beholder to make his own interpretation of the appearance. It took many centuries for the professional artist to reach this point. Now the mass of the public are following the same road; they reach out for pictures that shall give pleasure rather than information. In the case of photography there are many ways to this end, one of which is to avoid an unnatural definition. The ideal desired is to give a picture as the eye sees it. In the nature of things it is an impossibility; consider the eye viewing a landscape: It is apprehended through a lens of short focus and very limited field. With great rapidity its different objects and masses are focussed, examined in turn; attention is evoked by some; others never enter into consciousness; presently a visual concept is formed in which the objects that have stimulated the attention most are dominant. Usually one particular mass or colour makes the greatest impression and holds the optical focus around it, all other things fade away with only a subconscious memory of their existence. As different observers will probably have their attention fixed by different objects in the same field of view, the mental picture will be correspondingly different. An artist using paint will seek to reproduce his impression with such success as his skill permits and within limits he may partially succeed. He does not paint what his eye has not noticed, and he can hardly help giving extra prominence to the things that have mostly impressed him. By enhanced colour contrast, chiaroscuro, or even departure from strict perspective drawing, this is easily attained. How far can the user of the lens follow in his footsteps?

In this article we will confine our attention to one means only, namely, modification of the image in order to secure concentration of attention on the subject of the picture. This means, subordination of the unimportant. Where the conditions permit of it, selection of view point will attain much, but more can be effected by the character of the photographic image. The problem is not easy. It is to see the main object clearly, even sharply, and the rest according to their lesser values. The definition of the main object is easily attained by focussing on it, but most pictures contain many planes, and to get any resemblance to natural appearances they must be shown with reasonable definition, that means stopping down, which in its turn means the excessive sharpness of all objects; the curse of most photographs.

There are three ways by which an approximation to a solution may be obtained. They are—first, coarse focussing; second, the use of a pinhole; third, using a lens that is uncorrected, that is, possesses naturally defective definition.

The first method was much in use some ten or more years ago. To be effective it requires too much blurring of the objects of secondary interest. With a few subjects it gives pleasant results. In a general way it gives not only softening of texture but blurring of outlines, and this is fatal.

The use of a pinhole to form the image is another matter. The definition of a pinhole picture is determined by the size of the hole employed. A No. 12 needle hole gives a circle of confusion of 1/100 of an inch, which is what is demanded of a lens, but the exposure time is prohibitive; a No. 10 needle hole 1/50 of an inch, gives a definition answering all requirements of landscape and portraiture. The picture made in this manner has unique character, all objects are in focus from a few inches to infinity. They are equally in focus. The drawing in absolute perspective. The angle of view is determined by the size of the plate. The definition (with No. 10 hole, No. 3 Power-Watkins System) is clear but soft, much as the eye sees it. These are great advantages, and those who have learned to use a pinhole rarely discard it; but there are grave disadvantages. The exposure time is about 60 times that of an $f/8$ lens, and the equality of the definition through all planes forbids all selective focussing. In landscape this is usually an advantage, but in many cases it is the loss of a means of accent.

The third method, the use of an uncorrected lens, is due to Major Puyo, of Paris, who some fifteen years ago advocated the employment of spectacle lenses, and induced a French firm to make them of dimensions not used by the oculist. A spectacle lens is not corrected for spherical aberration astigmatism, coma, or chromatic aberration; the meaning of which is that besides the main image various secondary images are formed that overlap the former and, according to the amount, soften or blur the image formed on the negative. Now the amount and position of this blurring can be controlled in various ways and can even be relegated to the centre or periphery of the visual field, or, by the use of very small stops, practically eliminated. The success of the French lenses led the well-known lens makers to introduce lenses of this type, until the soft-focus lens is more and more displacing the anastigmat for art as against scientific purposes.

The last lens of this type to enter the field is the Kalosat, the outcome of a communication contributed to "Camera Craft" by the writer of this article, in November, 1919. In the search for a lens of great rapidity to take instantaneous photographs in room lighting, the writer employed a quartz spectacle lens. The reasons for the choice were that as there are only two surfaces as against eight or sixteen in anastigmats, the loss of light by reflection is reduced to a minimum, and as quartz or oxide of silicon passes the highly actinic ultra-violet rays, their action could be counted on to help produce the image. Lastly, as the refractive index of the silica is only one-tenth that of lens glass, a focal correction is not necessary.

The experiments were made with a $1\frac{1}{4}$ in. meniscus lens of 5 in. focus, concave surface towards the field, working aperture being thus about $f/4$. The results were most satisfactory and portraits taken 8 ft. from the window of a living room at one-sixteenth of a second were excellent in definition and permitted of enlargement from $3\frac{1}{4}$ x $4\frac{1}{4}$ to 14 x 17 without loss of quality.

At that time, some seven years ago, a lens competition exhibit was being hung on the walls of the California Camera Club, and the writer hung these enlargements with the caption, "It's all in the lens, price 50 cents," without suffering from the comparison with the product of well-known lens makers. Shortly after, trying it out on landscape, the lens was lost, and the attempt to replace it by another pebble lens, that is quartz lens, resulted in failures owing to imperfections in the natural rock crystal from which they are made.

This led to the discontinuance of pebble lenses, and nothing further was done until the writer learned that rock crystal synthetically made, and therefore flawless, was used for lenses in the transmission of light for medical purposes. A request to make a 5-in. lens from the makers was responded to, and the results obtained by its use were given to the photographic world in the article in "Camera Craft" two years ago. The result was an immediate interest both in the U.S. and abroad that finally caused the manufacture of the Kalosat lens.

It is made in two series, one working at $f/4$, the other at $f/6.5$, but the rapidity of the lens is such that allowance must be made for it in making exposures by meter. Experiments with the $f/6.5$ lens in landscape work yield good marginal definition and an unexpected flatness of field. Single lenses of

the meniscus type show inward or outward distortion of straight lines near the margin of the picture, but this is practically eliminated by the forward position of the diaphragm, and buildings show no distortion.

The writer devised this lens for rapid action, which it has, but the makers especially market it as a soft-focus lens, and it is being judged largely from this standpoint, and this calls for some explanation and warning. The softness in such lenses is due to the overlapping of the central image by marginal images of slight intensity. If the lens is stopped down too much the latter are cut out and the definition becomes proportionately sharp. Furthermore, with such lenses the focussing must be done after the diaphragm has been selected, it varies with the aperture. Failure to observe these rules will result in failures for which the lens is in no way to blame. It has been stated that in the case of crystal lenses the foci of the actinic and visual rays so nearly coincide that no correction by drawing back the lens is needed, but they do not completely come together, and this adds to the softness of the image. If the user rack the lens back 1-400th of its focal length he will lose this diffusion. Therefore, when using the lens for softness be careful that the lens is in front rather than behind its visual focus. Lastly, the distribution of the area of softness in this type of lens depends on the relation of the curvature of the lens to the plate and field. If the convex side of the lens is towards the plate the diffusion is evenly distributed and no area is critically sharp. This is usually the right position for general use. If the lens be reversed we obtain sharp definition in the centre and rapid shading off into blurring at the edge. Such an arrangement may be an advantage in portraiture.

These warnings are necessary, as only recently we received a letter from a gentleman, presumably of experience in photography, stating that "he did not think much of the Kalosat as a soft-focus lens in comparison with the pinhole," oblivious of the complete difference, both in nature and field of usefulness of those instruments. My own experience with crystal lenses enables me to say that they will give excellent results in all fields, except the purely technical and in copying; that pictures taken with them are much closer to what the eye observes than those of the older type; that the Kalosat is the most rapid lens made, *par excellence* a portrait lens, but reliable in landscape work.

H. D'Arcy Power, M.D.

THE IDEAL STUDIO.

I was wandering aimlessly in a strange part of the country; how or why I came there I had no idea, neither did I know, nor could I conjecture my whereabouts, but the names over the shops and even the costumes were British, but then, in the colonies they could be the same. It was while noting the names that my eye was caught by a window in which photographs were displayed and my attention was at once riveted by such specimens of the photographic Art (with a capital A, Mr. Printer) as had never before met my gaze. Having been connected with photography for over fifty years, I have seen many thousands of pictures produced, both in this country and abroad, but never before had I seen perfection. Yes, I speak advisedly, for after carefully inspecting the specimens in question for some minutes with the purpose of searching out any technical or artistic fault I was compelled, *nolens volens*, to admit that they were one and all, without fault or blemish. They were monochrome prints of a pleasing tint, perfect in posing, lighting, exposure, development, printing, even to the slightest detail of mounting, and I gazed upward to see the name of the genius who had so far superseded his fellows. It would seem he was not particularly egotistic, for the facia bore the simple inscription, "The Ideal Studio."

Anxious to know more, I passed through the open door, and found myself in what appeared to be a large drawing room one could hardly call it a studio, for it apparently contained none of what are generally acknowledged studio appliances and accessories. The chairs, tables and furniture in general were such as might be found in any middle-class or fashionable drawing-room. There was no camera stand or camera visible, and there was an entire absence of painted backgrounds, balustrades, etc., etc. There were no glass windows on either side, but in the very centre of the room was what seemed to be an enormous, many-sided lantern, and it was evidently from this, and this alone, that the lighting of the apartment was obtained.

As I entered a suave, elderly gentleman advanced to meet me, and, giving me greeting, asked me if I desired to make an appointment. To this I replied that, although I had not come for that purpose, still I should be very pleased to have a sitting. Then I explained to him that I was a photographer myself, and that, having been attracted by the beauty of his specimens, had entered in the hope of being enlightened as to his methods of production.

"I am pleased, indeed, to meet a brother photographer," he replied, "and certainly have no objection to giving you an insight into the methods in use in what I have called the Ideal Studio, but you will bear in mind that whatever standard of excellence I may have reached so far is as nothing to what I hope to be able to produce in the future. I have an appointment for a group of three children almost directly, so that you will be able to see at once how I work the lantern, which, you see, is my sole source of lighting, and the rays can be thrown on any part of the studio by merely touching one of these switches, indicating, as he spoke, a series of small studs along the wall on the right-hand side of the apartment. Rapidly manipulating the same the light (and what a light!) was made to traverse the whole of the chamber, now up, now down, now on the right, now on the left.

"You will notice," he said, "that the light itself is of a pure white, and I may say that, although it is actinic as the brightest sunlight, it is still as soft as sunset."

Then, taking from a side table what appeared to be a camera of the reflex type, he continued,

"This is my camera with which the main part of my work is done. You will observe that it has two lenses. They are, so to speak, twins, but instead of producing two pictures they are so accurately manufactured and at the same time so accurately set that they produce only one, and as the lenses are practically reproductions of the human eye, the one picture produced is absolutely stereoscopic. The power of the wonderful light in which radium plays a great part, and the rapidity of the special plates I use in addition, obviate any chance of movement showing, either caused by instability on the part of the sitter or by oscillation of the camera; in fact, I can allow the camera to swing, and the rapidity of the exposure is so great that the picture will still be perfectly sharp and clear."

Just then a lady and three children were ushered into the studio, and the proprietor at once commenced to make himself agreeable to the youngsters, passing playful remarks, and asking if they had come to see his toys. Naturally, they looked round for the toys, which, so far, were not in evidence; but with a cheery "come on," he led them across the apartment, and, motioning the eldest, a girl of about ten, into a low basket chair, he indicated to the two younger boys—that they should take up position on the floor at her feet. I could not but notice with what ease they at once seemed to take up natural and easy positions, and that without any attempt

on his part to pose them or control them in any manner. Then, still smiling, he opened a small cupboard close at hand, from which he extracted two or three toys, which he handed to the children. But what toys they were: not the general type of thing, but something quite unusual; toys that, from their very novelty, at once drew the rapt attention of the kiddies. Then, on his touching a switch at the side, a panel behind the group drew up, revealing a recess containing all the appurtenances and appliances of a child's day nursery, and forming a thoroughly realistic background to the children. He then stepped away, still talking to them in a jovial manner, and, taking up the camera, there was a momentary click, after which he suggested that perhaps they would like to see some different toys. They at once followed him to another part of the studio, where a totally different pose was obtained without any attempt at control on the part of the operator, and the panel at the back this time revealed a different type of background.

He did not hand them toys now, but, taking one in his own hands, which appeared to be a doll as large as an ordinary baby, he laid it on a table in front of him, the children meanwhile watching his every action with intense interest.

"You see," he said, "this is a musical doll, a doll that goes to sleep when it lies down, but when I stand it up it at once commences to sing," and, suiting the action to the word, he stood the doll on its feet.

Whether it was a case of ventriloquism, or whether the doll contained something in the nature of a gramaphone, I could not tell, but the strains of a popular melody at once became audible. At once there was another "click," and the picture was taken.

The lady having expressed a desire to be taken also, a couple of exposures were made upon her; the first, with hat and jacket, was posed in front of a recess which represented a conservatory, and the second in an up-to-date boudoir. Again I noticed that all the posing was obtained by suggestion only, and that in each case it was perfect.

An intimation was then given that the sitting was over and that proofs would be sent during the evening, and the proprietor of the "Ideal Studio" and myself were once more left alone.

"Now," he said, "you will see the next part of the procedure." And, so saying, he opened a door close at hand, and we passed into a small lobby, and the door was closed again, while another door in front was opened, and we now passed into a second apartment; but what could it be? It certainly bore no resemblance to any kind of dark-room that I had ever seen. In the first place, it was filled with a radiant light, that appeared equal to ordinary daylight, but its colour was indefinable. It certainly was not ruby, neither was it green or white; then there were no sinks and no water, no developing dishes, and very few bottles on the shelves. Instead of these, there were long benches on either side, and on these benches what appeared at first sight to be one or two gas ovens.

Placing the camera on one of the benches, the operator opened the back and commenced to take out the exposed plates.

"But," I exclaimed, "how about all this light?"

"Oh," replied he, "that is all right; this light is absolutely non-actinic, and will not fog the most sensitive plates yet produced. Here, again, radium plays its part, but in a different combination from the light of the studio."

He then proceeded to place the plates in an open rack, and, opening one of the ovens, placed the rack inside, closed the door, and touched a switch at the side

"There," he remarked, "in ten minutes from now those plates will be developed and fixed and ready for printing."

"But," said I, "you have not put them in any developer yet."

"Well," he replied, "my system of development is an adaptation—in fact, an improvement—on the old Daguerreotype process. These plates are developed by fumes and without wetting. The gentle heat which generates the fumes in that oven is not sufficient to reticulate the softest gelatine film, and, as every exposure is always the same and every plate I use of the same rapidity, ten minutes is always the time occupied, and the fixation going conjointly with development, they will be quite ready in that space of time, especially as no washing is required, for no trace of anything deleterious remains in the film.

"We shall just have time to partake of a glass of wine and a biscuit, and then our negatives will be ready for printing," he continued, "and by then my next appointment will be due."

"But," I queried, "how about retouching?"

"Therein lies one of the best points of my system," said he, "for the exquisite softness of the light obviates all necessity for retouching. Admitted that at times there may be a scar or some similar marking which may require just a touch but even that is of so rare an occurrence as to be almost a negligible quantity."

Having consumed our refreshment, we proceeded to examine the negatives, which were certainly the acme of perfection, both technically and artistically. My host then opened what appeared to be a second oven, but very much longer than that in which the plates were developed.

"This," said he, "is my printing apparatus. The negative is placed in position at this point," suiting the action to the word, "and the bromide paper superimposed. You will observe that the paper is already mounted, there being no moisture during development to cause trouble."

So saying he produced from a box at his side a series of mounts, on each of which the paper was already affixed in position. One of these was placed on the first negative, once again the oven was closed and a switch touched. Almost immediately it re-opened to receive the second negative, and so on through the series.

"Now," he said, "these negatives are printed automatically, each print receiving exactly the same exposure, and they then pass on down the oven at a specially-regulated speed over the fumes of the developing and fixing compound, and in a few minutes will be deposited at the other end the finished production ready for delivery. Such is the process in daily use at the "Ideal Studio."

"In the next room I have installed what I call my publishing machine." And passing through another doorway we entered an apartment, down the centre of which ran a third of the oven-like contrivances, but of a much more massive construction.

"In this," he continued, "are printed, developed, and toned my series of postcard local views. In this end, you observe, is a framework, taking six negatives, each space being accurately bordered and spaced. In this box above I can place up to 500 sheets of the sensitised board, each taking six postcards and making three thousand in all, though I scarcely ever have a run of so large a number of one subject. These sheets drop automatically into place as the machine works, the back comes up and presses them into contact at the same moment that the radiolite is exposed upon them, and they then pass on as in the smaller machine, through the developing, fixing fumes into the fumes of a preparation of sulphurous acid, which yields a fine brown tone, from there through more fumes which eliminate any acid that may be left on the film, which, as you see, is of a high enamel surface, and as that surface is in no way affected during the various processes, there is no glazing required, which is another saving effected. This machine I can start going at any time and leave in action any length of time, knowing that after the exact space of one hour 6,000 cards are being automatically deposited in a receptacle at the other end every hour that passes. And now having demonstrated the methods I will write you out the formulæ." So saying, he took a seat at a desk, drew pens, ink and paper towards him, when some wretched tootler outside started "Bubbles" on a cornet, and I woke to find myself in bed at home without my formulæ, and also without any knowledge of the whereabouts of "my dream studio."

C. Brangwin Barnes.

Assistants' Notes.

Removing Amidol Stains From Finger Nails.

Immerse the hands in a solution of sodium sulphide about double the strength of the usual sepia tone until the deposit on nails can be removed by gentle scraping. This should occur in two or three minutes; after a rinse under the tap the hands are transferred to a weak permanganate bath, followed by a short immersion in metabisulphite to remove any permanganate stain. A final wash with soap and water completes the process. I have used above method repeatedly for the last two years and have noticed no ill-effects either to hands or nails, and in my own case it has been surprisingly successful.—A. Graham Brown.

[We would add a caution against using sulphide without the after-process recommended by our contributor, doing so because sulphide alone will discharge pyro stain, and, therefore, some people may be tempted to use it.—Eds. "B.J."]

Factorial Development.

The prominence of factorial development given by one or two workers during the last twelve months, and Mr. Watkins' repeated appeals to the professional photographers generally for some of their experiences with it, prompts me to send the results of a few tests I made a few months prior to the war.

They were made to find out any differences that varying the quantities of soda carbonate to each grain of pyro might have factorially and with regard to stain.

The required number of quarter-plates were exposed as rapidly as possible on a suitable subject to a tested steady daylight, giving a full exposure and using a roller blind shutter to ensure regularity.

The developer used was as follows:—

A.—Pyro	.....	1 oz.
Potass. metabisulphite	.....	50 grains
Water	.....	9 ozs. 1 dram
B.—Soda sulphite, soda (cryst.)	.....	2 ozs.
Potass. metabisulphite	.....	2 drams.
Water to	.....	10 ozs.
C.—Soda carbonate (cryst.)	.....	2 ozs.
Water to	.....	10 ozs.
D.—Potass. bromide, 10 per cent. solution		1 oz.
Water	.....	5 ozs.

Solution C is best kept apart from the sulphite, and the above keep well for some time.

Solution B is the "B.J." neutral sulphite one, C is made of similar strength for convenience of measuring.

Grains of Each Component per Fluid Ounce of Complete Developer.

	Pyro.	Neutral Sulphite and Soda Carbonate—each.	Bromide.	Factor.	Remarks.
1	1	4½	—	24	Good.
2	1	6	—	18	Fair, slight over-development.
3	1	9	—	16	Good.
4	1	12	—	14(?)	
5	1	18	—	14	Good.
6	1	24	—	12	Good.
A	2	9	—	12	A little too contrasty.
B	2	12	—	8	Good.
C	2	18	—	8	A little too contrasty.
D	2	24	—	6	Good.
E	2	36	—	5½	Good.
F	3½	17½	—	9	Good.
G	1	6	¼	7	Good.
H	2	12	¼	5	Good.
I	2	24	¼	5	Good.

The above factors proved very useful to me, others may need to vary them for their own class of work.

Only one ounce of freshly mixed developer was used for each plate.

The time of appearance was noted, dish covered, and rocked at intervals of 40 seconds till development was complete, rinsed quickly for a few seconds only, and put in fresh hypo.

Measure and dish were wiped out each time after use.

Keeping the carbonate separately makes a lot of difference in the prevention of stain, and there was no stain in any of the above; the printing quality was also good. 5, 6, D and E gave almost similar results and a trifle softer than the rest.—G. J. W. W.

Photo-Mechanical Notes.

Contact Reproductions by Reflected Light.

Considerable interest is being taken in the photo-mechanical journals in the process which has been patented by a German inventor named Max Ullmann, and to which the name of "Manul" has been given. The process provides for the reproduction of printed matter, letterpress, etc., without the use of a camera and even when the "copy" has printing or other matter on both sides. It will be seen that essentially the method has a strong family likeness to the process of the late J. Hort Player, published in this country some fifteen years ago. It has, however, been made the subject of various patents, in particular the German Patent No. 287,214, of August 13, 1913. M. L. P. Clerc, in giving an account of the process in the current issue of "Le Procédé," points out that the method of making copies by contact and by reflected light was indicated by Yvon about 1890, and more recently by M. G. de Fontenay. In the Manni process, however, the dry-plate or bromide paper emulsion employed by those who had previously experimented in this method is replaced by a film of bichromated colloid coated on glass. Although we have not seen any of the results of the Manni process, we are told by those who have that while the lines of a negative are by no means clear glass, the ground has considerable opacity, the contrast of the negative as a whole being fairly satisfactory.

The sensitive plate is placed in a printing frame with its uncoated side in contact with the glass of the latter. The drawing or letterpress to be reproduced is then laid face down on the sensitive surface, and, the back of the printing frame having been inserted, exposure to light is made. In these circumstances the light which passes through the sensitive film is absorbed by the dark parts of the drawing or letterpress to be reproduced, whilst it is reflected back into the sensitive film by the white portions of the original. Roughly, it may thus be said that the light acting upon the bichromated colloid in contact with the white parts of the original is about double that which acts upon those parts in contact with the lines or characters of a black and white original. It will thus be understood that if the exposure is correctly adjusted the bichromated colloid may be rendered insoluble in the parts representing the white portions of the original and left of a sufficient degree of insolubility in the portions in contact with the dark parts of the original.

After development, by removal of the soluble parts of the colloid, a relief is thus obtained, and may be stained with a suitable dye in order to obtain a negative of exactly the same size as the original, but reversed as regards right and left. The patent specification does not give instructions in the preparation of the sensitive film, the inventor reserving to himself the supply of the necessary sensitive plates to licensees under his patents.

Recently, however, Professor August Albert, of the Institute of Graphic Arts in Vienna, has published in "Photographische Korrespondenz" particulars of the formulæ and procedure which he has found to yield satisfactory results. The relatively thick film of bichromated gelatine, such as is employed in carbon printing, is quite unsuitable for the process. It is necessary to employ an extremely thin film, and to render this completely insoluble by prolonged exposure to light, solubility of the exposed portions being at the same time obtained. The two following formulæ have been found to yield excellent results:—

(1) 25 c.cs. of a 14 per cent. solution of albumen or white of egg, previously beaten to a froth and filtered, are mixed with

20 c.c.s. of clarified fish-glue, as employed in the enamelene process, and 10 c.c.s. of 20 per cent. ammonium bichromate solution added.

(2) A mixture is made of 60 c.c.s. of water, 30 c.c.s. of liquid fish-glue, 24 c.c.s. of 10 per cent. ammonium bichromate solution, and 2.5 gms. of sugar candy, previously dissolved in 20 c.c.s. of water. A few drops of glycerine may be added.

One or other of these preparations is coated on glass by means of a whirler, the film being extremely thin, and almost colourless.

The time of exposure requires to be very carefully determined. In first trials of the process it is well to use a perfectly constant source of light, placing the printing frame at a given distance therefrom alongside an actinometer. During the exposure a card is placed step by step against the printing frame at noted intervals of time, and the reading of the actinometer made each time that the card is shifted into a fresh position. In this way the plate is given a series of step known exposures corresponding with the readings of the actinometer.

Development is done in cold or luke-warm water, and the plate is then immersed in a solution of a red-dye, such as fuchsine, and afterwards into one of orange colour such as chrysoidine, so as to obtain intense and completely non-actinic dyeing of the colloid relief. After a brief rinse the negative is dried, and is then used for printing on metal by one or other of the customary processes.

The following patent has been applied for :—

PRINTING PROCESSES.—No. 26,926. Photo-mechanical printing processes. A. R. Trist.

FORTHCOMING EXHIBITIONS.

September 19 to October 29.—Royal Photographic Society. Secretary, Royal Photographic Society, 36, Russell Square, London, W.C.1.

November 17 to 19.—Bowes Park and District Photographic Society. Particulars from the Hon. Sec., S. Smith, 68, Mannock Road, Wood Green, London, N.22.

November 23 to 26.—Rotherham Photographic Society. Latest date for entries, November 9. Particulars and entry forms from the Hon. Exhibition Secretary, Sydney G. Liversidge. "Orissa," Gerard Road, Rotherham.

December 3 to 17.—Scottish Photographic Circle. Hon. Secretary, W. S. Crocket, 10, Parkgrove Terrace, Tollcross, Glasgow.

1922.

January 21 to February 4.—Partick Camera Club. Latest date for entries, January 30. Particulars from the Hon. Secretary, James Whyte, 51a, Peel Street, Partick Glasgow.

February 14 to 17.—Exeter Camera Club. Particulars from C. Beauchamp Hall, Hon. Exhibition Secretary, Exeter Camera Club, "St. Denys," Bellevue Road, Exmouth.

February 11 to 25.—Scottish Photographic Salon. Particulars from the Secretary, James F. Smellie, Braefindon, Allanshaw Street, Hamilton.

SCOTTISH PROFESSIONAL PHOTOGRAPHERS' INTER-CITY GOLF MATCH.—An interesting golf match, between the Glasgow and District Professional Photographers and the Edinburgh Society of Professional Photographers, took place at Turnhouse on Friday, October 21, 1921. The members were fortunate to have fixed on an ideal autumn day for their outing. The course and the greens were in excellent order. The match between the clubs was played in foursomes, and, after some good play, resulted in a draw. The members in the afternoon engaged in friendly matches, which were much enjoyed by all. The visitors were in the evening entertained to dinner by the Edinburgh Society, under the chairmanship of Mr. J. R. Coltart, who, in proposing the toast of "The Glasgow and District Professional Photographers' Golf Club," said that of all the golf matches played between the Societies, this one was, without question, by far the most enjoyable he had attended. This was no doubt accounted for by the ideal autumn day and the fact that the match had ended in a drawn game.

Patent News.

Process patents applications and specifications—are treated in "Photo-Mechanical Notes."

Applications, October 10 to 15 :—

FILMS.—No. 26,771. Manufacture of photographic films. P. A. Barron.

SHUTTERS.—No. 27,451. Photographic camera shutters. A. E. Bettles.

APPARATUS.—No. 28,352. Apparatus for use with photographic processes. C. Callebaut.

PRINTING-APPARATUS.—No. 27,198. Photographic printing apparatus. H. R. Eason.

PRINTING-FRAMES.—No 27,363. Photographic printing-frame, etc. H. McClean and W. H. U. Morley.

CAMERA DEVICE.—No. 27,101. Means for positioning sensitised cards, etc., in photographic cameras. E. F. Stratton.

LENS-HOLDER.—No. 27,111. Combined lens-holder and shutter for photographic cameras. E. F. Stratton

---

COMPLETE SPECIFICATIONS ACCEPTED.

These specifications are obtainable, price 1/- each, post free, from the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C.

The date in brackets is that of application in this country; or abroad, in the case of patents granted under the International Convention.

FOCUSSING MECHANISM.—No. 169,249.—(June 19, 1920.) The invention relates to improved means for coarse or fine adjustment of focus.

In a mechanical focussing device especially adapted for photographic work it has been proposed to mount the movable member upon three rollers, two of which are V-grooved peripherally to run on a rail, whilst the third is plain.

According to this invention the means for coarse adjustment comprise a sliding member of the instrument, adapted to carry the lens or object to be focussed, and having a three-point bearing on a supporting member of the instrument, the bearing

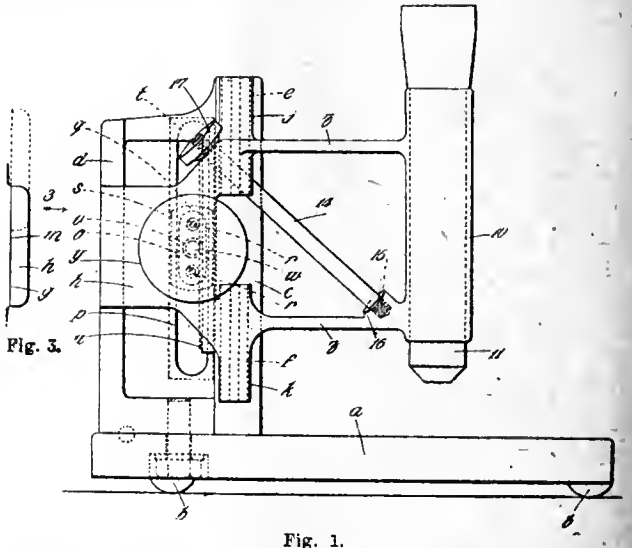

Fig. 3.

Fig. 1.

surfaces of the sliding member and the supporting member being rigidly attached thereto respectively, two of the pairs of the coacting bearing surfaces being of V-type, whilst the other pair is of flat type.

Preferably the two bearing surfaces of V-type are in alignment, the one with the other. Preferably also the coacting bearing surfaces of each pair are of equal length, and so arranged that when in use they normally travel so as to overlap equally at each end in order that the surfaces may remain straight in spite of wear.

The means for fine adjustment of focus comprise two resilient bars, adapted to support the lens or object to be focussed, and set normally parallel with one another and at right angles to the direction of motion required in combination with means for springing them in this direction from their normal positions.

In the drawings, on a base *a* supported by three feet *b* is an upright member *c* integral with a frame *d* substantially semi-circular in horizontal cross-section. On the side of the member *c* and frame *d* are V-grooved and flat bearing surfaces respectively, the V-groove bearing surface being divided into the two open-ended parts *e* and *f* of equal length towards the top and bottom of the member *c*, whilst the flat bearing surface *g* is arranged at a height midway between those of the parts *e* and *f*. Coacting with these bearing surfaces *e*, *f* and *g* are corresponding bearing surfaces on the sliding member *h* of the instrument. The V-bearing surface on the sliding member *h* is divided into two parts *j* and *k* of the same length and separation as the grooves *e* and *f*, whilst the flat bearing surface *m* on the member *h* is of the same length as the surface *g* on the frame *d* (see fig. 3). In this manner a three point bearing is provided, whilst the equality of length of the coacting surfaces at each point, and the fact that they normally travel so as to overlap equally at each end ensure that, when in use, the surfaces may remain straight in spite of wear.

The member *h* is held to the frame *d* by a boss *n* integral with the member *h* and having a flatted portion *o* which passes

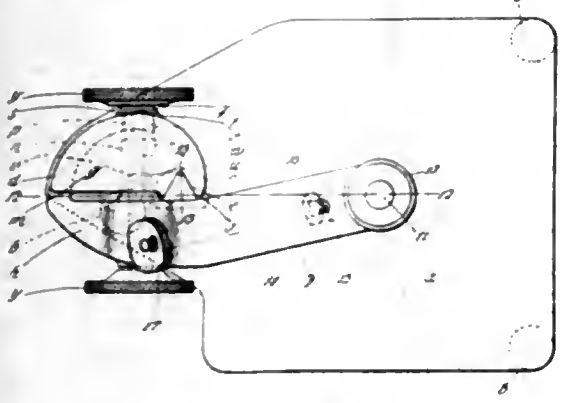

Fig. 2.

through a slot *p* in the frame *d* and carries a guard *q* secured to the boss *n* by screws *r*, *r*, a spring *s* being disposed between the guard *q* and a bearing surface *t* at the edges of the slot *p*, so as to exert constant pressure on the parts and to prevent their coacting surfaces being separated under ordinary circumstances, and to take up wear automatically. The guard *q* serves to prevent the surfaces being separated to any harmful extent under force greater than that of the spring *s*.

On the member *c* is a rack *u* with which meshes a pinion *v* on a spindle *w* which passes through the member *h*, the boss *n*, the flattened portion *o*, spring *s* and guard *q*, the boss *n* being cut away at one side as at *x* (fig. 2), to enable the pinion *v* to engage the rack *u*, whilst knurled heads *y*, *y* are mounted at the ends of the spindle *w* to enable the pinion *v* to be turned to cause the member *h* to travel up and down for coarse adjustment.

Extending from the member *h* at right angles to the direction of its motion, and normally parallel with one another, are two resilient arms *z*, *z*, at the ends of which is carried a holder 10 for the optical element 11 to be focussed. The arms *z*, *z* are thin in the direction of motion of the member *h* and wide at right angles thereto so as to be deformed in one direction only. As will be seen from fig. 2, these arms *z*, *z* are so arranged that the bearing surfaces *e*, *f*, *g*, and the optical element 11 lie in or near to one plane 12—12 at right angles to the plane 13—13, intersecting the V bearing surface longitudinally, so that any force acting eccentrically and vertically near to the optical element 11 shall have a minimum tendency to displace either part *j*, *k* of the V bearing surface from its seating.

In order to effect a fine adjustment of the optical element 11 a rod 14 is mounted diagonally between the arms *z*, *z* being fixed at one end by screwing rigidly at 15 into the boss 16, is free to slide at its other end through a bearing in the member *h*, and is provided with a screw and knurled nut 17 which bears against the end of the bearing in the member *h*. By turning the nut 17 in the appropriate direction the arms *z*, *z* are sprung and the optical element 11 is thus moved slowly but rigidly in the required direction, i.e., upwards, and by turning the nut 17 in the opposite direction, the arms *z*, *z* are released to permit the optical element 11 to return to its former position relatively to the member *h*.

In this manner means free from shake or backlash are provided for fine adjustment of the focus.

The supporting and sliding members of the instrument may be held together by gravity, by a spring as shown, or by other constant pressure means, as may be most convenient, and it is preferable that, as shown, the V-bearing surfaces should be nearer to the optical element 11 than the flat bearing surfaces, since in this position they exercise greater control on the element 11.

Any convenient means other than the rack *u* and pinion *v* may be provided for effecting the coarse adjustment of the member *h*, for example a screw, and for springing the arms *z*, *z*, instead of the screwed rod 14 an eccentric or a differential screw may be used, or a diagonal strut itself adapted to be bent laterally may be substituted, or any equivalent means employed. William Taylor, Stoughton Street Works, Leicester.

SILHOUETTE PHOTOGRAPHS.—No. 169,233 (June 16, 1920). The object, *o*, intended for silhouetting is first photographed in front of a pure black background, *b*, the background appearing as a blank on the glass or whatever it may be, in accordance with the optical inversion of lights and shades.

The negative thus obtained is here called Nb_o, the lower letter representing the object and the upper the colour of the background.

Without changing the position of the object *o* nor that of the photographic apparatus, the black background is replaced by a pure white one, *w*, and another photograph taken. The new negative, Nw_o, accordingly shows a black background, while the figure appears negatively in the same way as on Nb_o. Of this second negative a diapositive is made, Dw_o, the object, *o*, appearing on the same as positive and the background as transparent.

By placing the diapositive, Dw_o, upon the first obtained negative, Nb_o, an altogether transparent background is obtained, but the object *o* is positive in one picture and negative in the other, and accordingly, by this superposition, a uniformly covered silhouette is obtained.

Instead of placing the negative on the diapositive, the two pictures may be photographically superimposed one upon the other. This may be done by first developing the negative Nw_o, leaving for the present the negative Nb_o undeveloped. Then the diapositive Dw_o, instead of being printed upon a new plate, is printed from the developed negative Nw_o direct upon the film or coating of the undeveloped negative Nb_o, so that after the development of the latter a complete silhouette will be obtained.

The taking of successive pictures before a black and a white background, as described, is, however, not generally practicable with objects which are in motion. In this case it is preferred to use one background of an intense colour, as, for instance, red. Avoiding as much as possible stereoscopic parallax, the object is simultaneously taken upon two plates, placing, however, before one of the lenses a plate of transparent material (i.e., a filter of the colour of the background, say, red), and before the other lens a filter of a complementary colour, for instance, green. Through the red filter the red background is photographically equivalent to white, and through the green filter to black. In this way the required partial pictures may, accordingly, be obtained by the simultaneous taking of two photographs, this last-mentioned way being specially adapted for cinematographic combination prints.

If the silhouettes, as described, are to be employed for combination printing, they should preferably be made on films as thin as practicable. Whenever, for instance, the object *o* is to be inserted into another picture, *a*, the negative of which may be called Na, we place a silhouette made as already set forth ($Nb_o + Dw_o$) between Na and the sensitive printing film and obtain in this way a print of *a*, in which the space for *o* is left blank. By means of the negative Nw_o, the ground of which is black and, therefore, requires no special covering, the object *o* may afterwards be inserted into this space.

Accordingly, in taking the first print there will be a superposition of the picture films $Na + Nb_o + Dw_o$.

Whenever circumstances permit, also in this case, as in the one described with reference to Nb_o and Dw_o, a photographic superposition

may be substituted in part, or even entirely, for the three mechanical superpositions between taking the three pictures, for instance, by taking the picture Nb_0 not upon a new film, but directly upon the undeveloped coating of Na, or both views upon one film.—Hans Goetz, 1 Sendlinger, Torplatz, Munich.

Trade Names and Marks.

APPLICATIONS FOR REGISTRATION.

EKUALITE.—No. 415,813. Cinematograph screens, specially prepared and framed. The Ekualite Screen and Accessories, Ltd., 5, Denmark Street, Charing Cross Road, London, W.C.2, manufacturers. June 1, 1921.

MARKS PLACED ON THE REGISTER.

The following marks have been placed on the register:—

KEROTYPE HONEYCOMB BRAND (DESIGN.)—No. 407,251. Photographic paper. Kerotype, Ltd., 2, The Pavement, Clapham Common, London, S.W.4, manufacturers of transfer papers.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

MONDAY, OCTOBER 31.

Bradford P.S. "Pictorial Principles." H. A. Crawford.
Dewsbury Phot. Soc. "My Rambles in Upper Wharfedale." Thos. Ryder.
Glasgow and W. of Scot. Amateur P.A. "The 'Black and White' Men." T. C. F. Brotchie.
Kidderminster and Dist. P.S. Midland Photographic Federation Slides.
Leeds Camera Club. "Enlarging and Reducing."
Southampton C.C. "Spirit Photography." Dr. McDougall.
South London Phot. Soc. "A Talk on London Landscape." A. E. Farrants.
Wallasey Amateur Phot. Soc. "Passe Partout Mounting." F. H. Lancaster.

TUESDAY, NOVEMBER 1.

Royal Photographic Society. Presidential Address. Dr. G. H. Rodman.
Birmingham P.S. "The Use of Colour Sensitive Plates." Kodak, Ltd.
Cambridge and Dist. Phot. Club. "Antarctic Exploration, with Notes on Polar Photography." Major F. Debenham.
Exeter Camera Club. "Ilford Lantern Plates and How to Use Them." Algernon Brooker.
Hackney Photographic Society. "Picture Making in Northern Italy." G. H. Dannatt.
Leeds Phot. Soc. Exhibition of Colour Transparencies.
Morley Photographic Society. Whist Drive.
South Glasgow Camera Club. "The Rocky Mountains of Scotland." John Martin.
Tyneside Photographic Society. Gaslight Printing.

WEDNESDAY, NOVEMBER 2.

Accrington Camera Club. "Carbro." A. Dordan Pyke.
Croydon C.C. "Necol Collodion Products." H. W. G. Bidgood.
Dennistoun Amateur Phot. Assoc. "Colour Lantern Slides." Paget Prize Plate Co.
Edinburgh P.S. "The Camera in Research Work." A. Eddington.
Halifax Scientific Society. "Bromide Enlargements: Chemical Modification." C. Thomas.
Ilford Phot. Soc. "Composition." M. O. Dell.
Partick Camera Club. Whist Drive.
Rochdale Amateur Phot. Soc. "How a Reflex Camera is Made." Messrs. Butchers.
South Suburban P.S. "Birds and their Nests." T. B. Bayne.
Tunbridge Wells Amateur P.A. "A Dive into Belgium." W. L. F. Wastell.

THURSDAY, NOVEMBER 3.

Camera Club, The. "Modern Magic." C. P. Crowther.
Hammersmith Hampshire House P.S. "Idle Thoughts of an Old Hand." P. R. Salmon.
North Middlesex P.S. Competitions—Prints and Slides, general.
Wimbledon and Dist. C.C. "A Loon in London." W. L. F. Wastell.

FRIDAY, NOVEMBER 4.

Wombwell and Dist. P.S. Beginners' Night.

SATURDAY, NOVEMBER 5.

Borough Polytechnic P.S. Dance, Edric Hall.

ROYAL PHOTOGRAPHIC SOCIETY.

Meeting held Tuesday, October 25. Mr. F. F. Renwick, F.I.C., in the chair.

Papers arranged by the Scientific and Technical Group were read.

Mr. F. C. Toy, of the Photographic Research Association, described experiments on silver bromide grains (of the same size and shape) made with the object of testing the hypothesis that the sensitiveness of such grains is equal. Triangular flat-plate grains were selected by visual examination at a magnification in the microscope of 4,000 diameters. Five were selected of approximate identity, their size differing from the mean by about 2 per cent. The thickness was estimated by observation of the focussing movement required to bring opposite faces into focus, the mean variation in volume being about 5 per cent., and the greatest variation in volume between two grains, about 25 per cent. The variation in size of the grains was thus about 1/30th of that in a process plate emulsion. It was found from sensitometric exposures that the characteristic curve obtained with the grains approximated to the typical H. and D. form, having a straight line mid-portion. The conclusion therefore appeared to be that uniformity of volume does not determine equal sensitivity. Mr. Toy dealt briefly with the theories co-relating the characteristics of the sensitive grains and the shape of the curve.

Mr. G. Brooksbank, of the Ilford Laboratories, followed with a paper on a cognate subject, viz., the visible change in silver bromide grains on exposure to light. He first showed an ingenious wedge-shaped vessel for coating glass with a 1-grain layer of diluted bromide emulsion. Photo-micrographs showed that the change in the grains from transparency to more or less complete opacity was independent of their size or shape. On treating the darkened grains with weak solution of hypo many of them were partly dissolved, triangular grains yielding skeletons of star form.

The two papers were discussed by Messrs. F. W. T. Krohn, R. E. Crowther K. C. D. Hickman, and the chairman.

In a third paper, Mr. Olaf Bloch briefly described a method of obtaining greater uniformity in the development of plates, in particular X-ray emulsions. The method consisted in the use of a roller made by removing the rubber from an ordinary roller squeegee and winding the wooden core spirally with thick-pile velvet. The plate was first covered with some developer, and the velvet-covered roller caused to travel constantly to and fro over the surface by its own weight. Mr. Bloch exhibited charts of the lines of equal density obtained in a plate by this method and showing an improvement over those produced by rocking the developer.

Mr. R. E. Crowther referred to the advantage, as regards uniformity of development, of pouring the developer constantly off and on.

The concluding paper, by Mr. Milts Cartwright, of the L.C.C. School of Photo-Engraving, dealt with provisional experiments on accuracy of reproduction in rotary photogravure and showed the very close approximation to facsimile rendering obtainable in the process.

Mr. H. M. Lomas, Mr. A. J. Bull, and Mr. E. L. Turner briefly discussed the paper.

CROYDON CAMERA CLUB.

Mr. K. C. D. Hickman lectured on "Some Aspects of Screen-Plate Photography," dealing in a highly interesting and fresh manner with a somewhat worn subject. By means of blackboard diagrams and coloured chalks he clearly explained the principles of the additive system of screen-plate photography, and emphasised the necessity of correct exposure, otherwise the ratios of the three primaries will be incorrectly rendered with material falsification of colour reproduction.

This was followed by practical instruction on working the Paget process, the whole lecture being delivered in the happiest of ways with flashes of genuine humour. Although a great admirer of the process he departs from the official instructions largely, even to employing Wellingtons S.C.P. plates for the positive transparency, a course which, it is assumed, Messrs. Paget do not recommend. It does not seem necessary to record these alternative procedures, apparently purely due to personal idiosyncrasies, for exquisite Paget

slides, secured in orthodox manner [illegible] Paget materials throughout, have often been shown in the club, notably by Mr. S. Rose.

An awkward cross-country journey compelled Mr. Hickman to leave comparatively early. It is intimated to him that after he had gone all sorts of complimentary things were said about the lecture and lecturer, more modified opinions being expressed about his slides. On the other hand, Mr Harpur felt hurt at a statement made that a plate became electrified and attracted the enemy when dusted with a brush. It was not necessary to use so much friction as to convert the plate into a high-tension electrical machine. To attempt to remove dust by knocking one end of the plate simply made holes in the table, and effected little beyond

Mr. Hibbert passed round an interesting novelty shortly to be placed on the market, a variant of placing tulle close to the lens, first suggested by Mr. Harpur many years ago. It consists of two cemented discs of glass enclosing a fine cross-screen of black lines, photographically produced, placed immediately in front of, or behind, the lens. He had tried such on a portrait lens, and the plastic quality of the softened definition was comparable with that furnished by the best soft-focus lenses. Discs giving three different degrees of diffusion will be supplied Obviously exposure will be somewhat increased; doubtless the makers will state the multiplying factors.

News and Notes.

Return of a "Quest" Photographer.—Two invalided members of the Shackleton Expedition, Mr J. C. B. Mason and Scout Mooney, arrived at Southampton on Saturday last from Madeira. The former who was one of the official photographers, became very ill during the voyage, but has now practically recovered.

The Malayan Camera Club.—We are interested in receiving the rules of the Malayan Camera Club recently established at Kuala Lumpur, Federated Malay States, the secretary of which, Mr. L. Arfeer, is an old reader of the "British Journal." We believe the society is the only one in the country, which includes in its white population large numbers of Europeans engaged in the rubber and tin industries

Photographs Wanted.—Mr F. W. Tassell, 39, Lowther Street, Carlisle, writes:—May I ask through the medium of your valuable paper if any firm of photographers who photographed the Australian cricket team, either in their private dress or cricketing flannels, would please communicate with me at once I wish to secure a photograph of the whole team that came over, or a separate photograph of Mr Armstrong and Mr. Gregory.

Lantern Slides in Schools.—A new catalogue of photographic and other lantern slides for the use of L.C.C. schools was issued last Friday. These slides, and the special viewing apparatus for the use of teachers, are housed in rooms adjacent to the Teachers' Reference Library, at the new County Hall, Westminster. There are 80,000 to 100,000 slides available for illustrating school lessons, and they are classified under 30,000 title subjects. The slides most in demand are, we are told those illustrating geography and history lessons.

A Much-photographed Bride.—When Mrs. Rosita Forbes, the famous woman explorer, and Colonel A. T. McGrath left the Chapel Royal, Savoy, last Saturday, after they had been married, they had to face 25 photographers As she was about to enter the chapel she halted to speak to the crowd of waiting photographers She remarked that she had said beforehand there were to be no photographs. Nevertheless, she smilingly agreed to let them take some at the conclusion of the ceremony. The majority of the guests departed before the photographic operations were over.

The Late Charles W. Hastings.—Late intelligence reaches us of the death on September 28 of Mr. Charles W. Hastings at the age of 71. It is so long since Mr Hastings was connected with photographic journalism as editor of the "Amateur Photographer" in the early days of that periodical that his kindly personality is probably a memory of only very few. For many years past he had been associated with the technical editorship of engineering and gas publications. He was a prominent Churchman and Freemason, and his death is sincerely lamented in circles more immediately familiar to him in recent years.

Smuggled German Cameras.—A fine of £174 was imposed on Henry French, Cedars Road, Clapham, yesterday at Dover, for smuggling 2,000 cigars, 1,000 cigarettes, cameras, binoculars, motor lamps and horns, etc., all of German manufacture. Most of the goods were in registered baggage that the defendant had marked "Armée Britannique," which the prosecution alleged was done to mislead the Customs. Invoices found on the defendant were stated by the Customs official to show that French did a considerable business with Germany. At the same Court, Sidney Dickenson, of Acton, was fined £5 10s. for smuggling a German camera.

Photographing a Petrified Forest.—The camera played a very important part in a geological discovery which has been made known by Dr. Venerosi, representing the Italian Government, by whom he was sent to the little village of Martis, in the north-west corner of the Island of Sardinia, to report on the rumoured existence of a petrified forest, said to be the most wonderful in the world The large collection of photographs which has been made show not only trunks of trees, but the foliage and even some fruit preserved through millions of years, and now lying exposed to view because the water which once filled the basin has disappeared.

A Too Early Photograph.—When sending photographs to a paper for publication it is advisable to write details on the backs of them or attach a letter to them. Messrs. Raphael Tuck & Sons, Ltd., have called attention to the fact that the reproduction of the Queen's Christmas Card which appeared in some editions of the "Evening News" last Friday should not have been printed till November 26. The editor states that the photographs were received by hand, and the letter naming the date of publication as November 26 was received by another department by post. As soon as the error was perceived the photograph was taken out of the paper.

Guilleminot Folio-Brom.—Mr. Jules de Gottal, 17, Cecil Mansions, London, S.W., writes drawing our attention to the Guilleminot product, for which he is the agent in this country, namely, the stripping "Folio-Brom" negative paper, which is coated with a rapid orthochromatic emulsion, and, owing to its paper support, is non halative. Moreover, the negatives are characterised by absence of grain, and the film can be retouched and printed on both sides, is not liable to be scratched, and is non-inflammable. Mr de Gottal is confident that photographers will find Folio-Brom to combine in itself the advantages of plates and films as regards both the quality of the negatives and the conveniences of manipulation for the purposes of portrait photography.

Lecture Courses in Optics.—The lecture courses to be delivered in the Department of Optical Engineering and Applied Optics of the Imperial College of Science and Technology, South Kensington, S.W.7, during the autumn session, include a general series on advanced optics and polarised light by Professor F. J. Cheshire. Professor Conrady will lecture on elementary and advanced optical designing and computing and workshop and testing room methods. Mr L. C. Martin will deliver a course on advanced optics and construction theory and use of optical measuring instruments. Further particulars are obtainable on application to the Registrar at the College The Director of the Department intimates that applications may be received from students and others desirous of carrying out research work in the laboratories.

Royal Society of Arts.—The winter programme of lectures at the Royal Society of Arts contains announcements of several series of great interest to photographers. Mr. F. F. Renwick, F.I.C., will deliver the Cobb lectures in May next, taking for his subject, "Modern Aspects of Photography." In February and March, Professor A. F. C. Pollard, formerly Professor of Optical Engineering in the Imperial College of Science, is to deliver three Cantor lectures on "The Mechanical Design of Optical Instruments." A lecture, which promises to be of photo-mechanical interest, is that by Mr. Arthur Wilcock on "Surface Printing by Rollers in the Cotton Industry." And in November-December Mr. Arthur M. Hind, assistant keeper of prints and drawings in the British Museum, is to deliver three lectures on "Processes of Engraving and Etching."

WINDOW ANTI-STEAMING COMPOSITION.—A correspondent writes:—In reply to a reader last week you stated (on page 636) that you did not know a certain window-cleaning composition, and gave some methods of preventing the steaming of windows. I know the product your correspondent inquires about, but do not know how it is made. I do know, however, that the following formula (advocated by a chemist on the staff of "Work") gives a paste similar to that your correspondent asks about:—Dissolve 100 parts by weight of finest coconut oil soap in water, boil to a clear jelly, and add, with constant stirring, 10 parts of tripoli, 5 parts of alum, 5 parts of cream of tartar, and 5 parts of white-lead, all previously pulverised finely and intimately mixed. Pour the mixture, whilst still hot, into shallow tin moulds, when it will quickly solidify on cooling. For cleansing, moisten the glasses with lukewarm water, apply the soap with a rag, and polish with a dry, soft cloth.

KODAK STAFF PHOTOGRAPHIC SOCIETY.—Although this society, which has been formed among the Kodak Company's staff, has been in existence for only a few months, it already has 170 members. On Thursday, in last week, it held its first exhibition for one evening only in the Oak Room, Kingsway Hall, Kingsway, London, W.C., when 328 prints were hung, catalogued and duly judged by Mr. W. L. F. Wastell. It might be thought that the exhibition of so many examples of work provided sufficient interest for the 3½ hours during which the room was open to members and their friends, but, on the contrary, the intensive programme which was squeezed into the time must surely fill the American Kodak staff at Rochester with doubts of their ability to "hustle" at as fast a rate. For, apart from an hour for refreshments, there was a formal presentation of awards, a lecture on fixing by Mr. Raymond E. Crowther, a demonstration of photo-micrography, and, incredible as it may seem, a lecture on radiography by Mr. Luboshez. We hope that visitors got an opportunity to look at the prints, many of which were of most meritorious quality.

HYPO-ALUM-GOLD TONING.—Mr. S. Zanoff, of the Towles Studio, of Washington, D.C., writes to "Abel's Weekly" that he has been experimenting for a long time trying to get away from the "sick-looking sepias that so many photographers produce," and that he has finally succeeded. He sends to our contemporary some Artura prints from negatives made by the Towles Studio. These, it is stated, bear out all he says about the process, which, by the way, can be worked on any paper. Mr. Zanoff's formulæ are as follows:—

TONING BATH.

No. 1 (A).—Boiling water (rain or distilled)	...	128 ozs.
Hypo	...	20 ozs.
Alum	...	2 ozs.
Boil for two minutes, allow to cool and then add		
Sodium phosphate	...	2 ozs.
No. 1 (B).—Nitrate of silver	...	60 grs.
Water	...	1 oz.
Potass bromide	...	180 grs.
Water	...	1 oz.

Pour the bromide solution into the silver solution and add precipitate and all to the cool hypo-alum bath. If silver and bromide are added to bath while hot, the latter will turn black.

Next add A to B.

No. 1 (C).—Chloride of gold	...	15 grs.
Water	...	2 ozs.

Finally add C to the mixture of A and B. This is Bath No. 1.

No. 2.—Water	...	128 ozs.
Hypo	...	1 lb.
Alum	...	4 ozs.

Boil 10 minutes and when cool add:

Water	...	1 oz.
Silver nitrate	...	30 grs.
Potass bromide	...	30 grs.

Have No. 1 lukewarm. Put prints in No. 1 for about seven minutes. Then rinse prints in clear water and then place in No. 2 bath until they turn sepia. Prints will tone evenly all over.

The prints should be printed the depth desired, a rich black and white, as they will not bleach by this process. The warmer the tone desired the less time the prints should be kept in bath No. 1 and the colder the tone desired the longer they should be kept in No. 1.

Commercial & Legal Intelligence.

LEGAL NOTICES.—A first and final dividend of 6¾d. in the £ has been made in the case of Charles Rose, picture frame maker (trading as Universal Framing Works), carrying on business and residing at 21, Chesterfield Road, Sheffield, Yorks. The dividend is obtainable at the Official Receiver's office, 14, Figtree-Lane, Sheffield.

NEW COMPANIES.

CONVEX ENLARGING AND METAL FRAME CO., LTD.—This private company was registered in Edinburgh on October 14, with a capital of £700 in £1 shares. Objects: To carry on the business of manufacturers of and dealers in embossed or convexed photographic enlargements and metal photograph frames, etc. The directors (each subscribing for the number of shares indicated) are:—J. B. Kellock, 141, Onslow Drive, Dennistoun, Glasgow, secretary, 200 shares; L. Mair, 17, Ross Avenue, Cardonald, Glasgow, picture frame maker, 300 shares; H. Hill, 60, Dunerium Street, Maryhill, Glasgow, manager of company, 200 shares. Secretary: J. B. Kellock. Registered office: 29, Oxford Street, Glasgow.

AMISOL, LTD.—This private company was registered on October 11, with a capital of £2,000 in £1 shares (all preference). Objects: To carry on the business of manufacturing photographers, etc. The subscribers (each with one share) are: T. Thomas, 1, Woodthorpe Terrace, Huddersfield, chemical engineer; S. Wilman, Norfolk Villa, Dewsbury, chemical engineer; W. Sowden, Fernleigh, 48, High Street, Cleckheaton, chemical engineer; T. C. Hammond, "Hopewell," Lightcliffe, chemical engineer; E. V. Chambers, The Manse, Lightcliffe, chemical engineer. The subscribers are to appoint the first directors. Qualification £100. Remuneration as fixed by the company.

Correspondence.

*** *Correspondents should never write on both sides of the paper. No notice is taken of communications unless the names and addresses of the writers are given.*

*** *We do not undertake responsibility for the opinions expressed by our correspondents.*

DESENSITISING WITH POTASSIUM IODIDE: FREUND'S METHOD.

To the Editors.

Gentlemen,—The communication of Mr. O. F. Bloch and Mr. F. F. Renwick in yours of the 21 inst., interests me much, but putting aside the "invitations" to do certain things, as outside the amenities of technical discussion, I may perhaps be allowed to make a few discursive remarks.

My recent paper on Freund's method is not intended to be exhaustive as regards the literature or in any other aspect, the papers which I mentioned being those which I regard as serviceable in calling more general attention to the method.

The communication of the above-named gentlemen in the "British Journal" (October 21, 1921) gives an addition to the experimental statements now available, and so is a gain; the conclusions arrived at are for a more matured study than that of a day, but the interest of the moment centres chiefly on the details which require amplification.

If I correctly read the particulars as to the iodising solution of Freund's strength, it is not quite as I described. In my view white potassium iodide cannot in the nature of things be pure, but alone it often is satisfactory. If, however, the final addition of two grains of soda crystals is made to a solution showing no tinge, we have an addition to existing alkalinity instead of an addition from which alkalinity is subtracted. There also appears to have been some confusion as to my suggestion of a possible (but not recommended) addition of one-tenth of potassium bromide solution to the developer, but in the experiments now described

this addition seems to have been made to the iodising solution. Further, a slow acting developer like the quinol sulphite developer should not be gauged by an equal-time action with the others, but by inspection in the manner which I pointed out. Sodium sulphate, if present, hinders or delays much, but accelerators other than the bromide in its reversed aspect may be used in accordance with established usages for hydroquinone, although I deprecate such additions. Most important of all, the gentleman mentioned gives no chemical notion whatever as to the nature of the sensitive plate which he used. Freund's original publication had definite reference to gelatino-bromide. I refer to a somewhat less satisfactory use of bromo-iodide, and I hope to return to this subject towards the end of this letter, or later.

Mr. Bloch and Mr. Renwick record their failure to find the word "gelatino-bromide" in connection with the reversing action of photographic plates as mentioned by Meldola in Watts's "Dictionary of Chemistry." That such skilled dialecticians should both fail in so easy a task appears to me remarkable, but I should not mention it were not the non-finding made the basis of an argument, which, if accepted, might materially affect the position. I suggest another glance at the place (Watts's "Dictionary of Chemistry," vol. iv., 1894, page 158); this time at the foot-note to the sentence ending " —— and in this case the potassium iodide is the photo-sensitive compound." Here Meldola calls attention to the strictly parallel but less pronounced case with potassium bromide.

Certainly I did not expect that any reader of the "British Journal" would require enlightenment as to so well understood a matter as the general distinction between the behaviour of a colourless and a coloured photolyte. Black-ness and white-ness are extremes and degrees of the same condition (see tabulation of Albedos, p. 3 of Vogel's "Das Licht im Dienste der Photographie," Berlin, 1894), and it is generally believed, and perhaps proved, that every truly ortho-chromatic photolyte must come in the range "Black to white." This general truth is subject to many apparent exceptions, owing sometimes to "colours" which happen to be outside our octave or so of vision, often owing to the embedding medium. Silver chloride, which appears to be itself totally insensitive to light but becomes a photolyte if a minute trace of moisture is present, is a remarkable instance. Also one may mention the apparent and perhaps real sensitising by weak iodine solution noticed by Andresen on p. 34 of his "Das Latente Lichtbild," Halle, 1913. There is much bearing on this subject in the writings of Abney about 1882, Watson's book, "Colour in Relation to Chemical Constitution," and Luppo-Cramer's "Photographische Probleme," Halle, 1907, and his subsequent works.

What surprises me most in connection with the communication of Mr. Bloch and Mr. Renwick is the apparent supposition that the change of silver bromide into silver iodide can by any possibility be complete.

In Field's method for estimating mixed chlorine, bromine, and iodine, the transformation may be, and indeed is, complete enough for ordinary analytical purposes. Gladstone's No. 3 law, however, holds good, and reverse transformations can be effected to a certain extent by taking advantage of the action of mass. Indeed, the action of mass is a factor of importance in many (perhaps all) interchange reactions between binary compounds, unless one product passes out of the field of action, as by precipitation or volatilisation. Such a transformation can never be complete, the case being analogous to that of a hyperbolic curve and the asymptote, as these may approach to infinity but can never meet.

To return to the concrete case of Mr. Bloch and Mr. Renwick. Personally I should not expect the solvents they mention to differentiate appreciably between the associated or combined silver halides, as in association they often lose some of their individual solubilities. Thus, for example, the easily soluble silver fluoride may be held rather firmly by silver iodide, and doubtless Mr. Bloch and Mr. Renwick remember the iodo-bromo-chlorides of Rodwell and their interesting properties.

If any chemical worker is interested in knowing how I recognised, or think I recognised, the stage by stage action of Freund's iodising solution, I will try and do the best I can for him if he will send me a reply postcard.

To revert to my efforts to secure gelatino-bromide plates as distinguished from plates containing iodine. The bromine was liberated in fractions from commercial sodium bromide (the safest, cheapest, and most convenient form in which to purchase bromine) by a modification of a method sufficiently indicated on p. 535 of Vol. I. of the Watts's "Dictionary" already referred to, and there associated with my name. The fractions (generally 11) are controlled by calculated amounts of sulphuric acid introduced through the thistle funnel. Ordinarily the freedom of the middle fraction from chlorine and iodine comes near to bromine purified from iodine by the method of Stas: a method described in the same column. Iodine-free bromine having been obtained no further details need be given, but any reader who would like a few words on any detail can send me a reply postcard, and I will do the best that leisure allows.

THOMAS BOLAS.

60, Grove Park Terrace,
Chiswick, London, W.4,

Answers to Correspondents.

In accordance with our present practice a relatively small space is allotted in each issue to replies to correspondents.

We will answer by post if stamped and addressed envelope is enclosed for reply, 5-cent International Coupon, from readers abroad.

Queries to be answered in the Friday's "Journal" must reach us not later than Tuesday (posted Monday), and should be addressed to the Editors.

E. JONES.—Prices paid for view postcard negatives are small, and range from 5s. to £1 1s. and upwards.

G. A. S.—The British patent specification for Rodinal developer is No. 1,736, of 1891, in the name of O. Imray, for the Actien Gesellschaft für Anilinfabrikation.

C. A. S.—We can think of nothing which would obstruct the action of the hypo except two or three coats of paint. We are quite sure that such a protective coating would not be penetrated by splashes of hypo.

E. C.—About the best book for quite a beginner is the latest one by Mr. R. Child Bayley, namely, "Photography made Easy," price 3s., through any dealer, or plus postage, from 20, Tudor Street, London, E.C.4.

W. H. REED.—Tables for the use of a tank formula for the "B.J." pyro soda developer were published by P. H. Dawson in "B.J.", July 9, 1915, pp. 445-446. You can see the volume in the library of the Patent Office, 25, Southampton Buildings.

G. LADE.—(1) Not positively harmful, but we would prefer to use an earthenware tap. (2) Yes, quite satisfactorily. (3) It could, but the usual formulæ keep very well, and are more energetic. (4) Not as a rule: prints from flat negatives might be benefited.

C. J.—The fault lies in not using a colour-sensitive plate. We advise you to use a good anti-screen plate, or, perhaps better, a panchromatic plate with a K2 or K3 filter for these subjects. So far as we can judge from the negatives you cannot improve matters by using a different printing paper.

G. H. H.—We are sorry that your letter has been overlooked. It is impossible to ascertain the maker's firm from the particulars you give. Apparently the lens is an ordinary rapid rectilinear of about 9 inches focal length and maximum aperture *f*/8, the diaphragm markings being evidently on the Uniform System. We should think the present value is not more than about £1.

S. N.—As your studio is so narrow you will require a good deal of glass if you want to secure any variety in lighting. We should recommend the two ends to be boarded over for three feet, the roof to be glass up to the ridge on one side, and the side light to come within three feet of the floor. This will give you 14 ft. run of glass. If you only want to work at one end, you can have 5 ft. boarded over at the camera end. This, of course, would still allow you to take heads-and half-lengths at either end.

S. D.—Judging from the specimens we should say the print is by the carbon process, much used for reproductions of paintings.

No doubt this particular tone and surface could be matched on one or other of the print-out silver papers, or, with greater difficulty, by sulphide toning bromide or gaslight paper, but we think that if you write to the Autotype Co., 74, New Oxford Street, London, W.C.1, they could indicate the tissue of theirs which would be a match of your print. You could, if you desired, make a print by the Carbro method.

W. E. J.—It is not very easy to account for the white markings from the particulars you give, but we think the most probable cause of the markings is actual eating of the gelatine film by insects. Such damage frequently occurs in this country, and is probably more likely to happen in the warmer climate of the Mediterranean. The remedy is to enclose the prints in a muslin chamber whilst drying, or, if you cannot do this, you might try giving them a final bath of weak carbolic acid, which perhaps may be enough to put the insects (if they are the cause) off their diet.

M. W.—It is difficult to make a studio roof remain watertight with ordinary putty, and we do not think red lead will be any better. A mixture of putty and Stockholm tar in equal parts makes a good joint, which never sets quite hard, and therefore does not shrink away from the wood. The putty must be good honest linseed oil and whiting. You will find particulars of various systems of metallic glazing in the advertisement pages of "The Builder." The sash bars are made of iron, and the lead strips are screwed upon them and turned down upon the glass, the edges of which are surrounded by the lead.

B. E.—The arrangement you suggest will answer very well, but you will have to place the sitter fairly close to the lamps if you wish to get exposures down to half a second. You will require reflectors behind the lamps and thin diffusers in front. The reflectors sold by the General Electric Company are very effective, and are fitted with oiled paper diffusers. We prefer thin calico diffusers, but are afraid that with 3,000 c.p. they would stop too much light. If you write to the General Electric Company (Magnet House, Kingsway, London, W.C.2) they will send you a catalogue with illustrations of these fittings.

W. T. S.—(1) If you wish to use flashlight you cannot do better than to get one of Charles's flash-lamps from Messrs. Griffin, but unless this is enclosed in a cabinet you will find the smoke troublesome for continuous work. We should recommend you to use half-watt lamps in preference to flash. We believe Messrs. Marion & Co. supply a fitting for adapting half-watt lamps to the Northlight umbrella. The same firm will also supply a small "point light" with stand. This can also be used for lamplight effects. (2) The postcard is undoubtedly liable to surcharge: nothing is allowed for a penny beyond five words of *greeting*.

W. W.—As a rule these old stains will not yield to the somewhat mild methods of soaking in acid, or other of the regular clearing solutions. We think you had better make a good P.O.P. print, or positive transparency on glass, so that if the worst happens you can make a copy negative. You might then try the effect of intensifying to a slight degree with chromium, using the C formula, page 439 of the current "Almanac." If the stains do not disappear under this treatment we are afraid you will have to give the negatives up as a bad job. Usually these yellow patchy stains are due to incomplete fixing, and there is no means of removing them if from this cause.

J. O. P.—(1) We do not know that naphthalene or camphor has a fogging or desensitising effect on plates, but, nevertheless, we should prefer not to put either of these substances in the camera case. If the case is kept regularly well brushed out, and the same applies to the bellows, there should be no reasonable chance of damage from vermin. (2) The only process of making colour prints on paper is by means of three negatives respectively exposed through red, green and blue-violet screens. These negatives are separately printed in blue, yellow and pink colours, and the prints superimposed on each other. The Raydex Company, 71, Lavender Hill, London, S.W.11, supply materials for a process of this kind, and issue a very complete instruction booklet.

Copyright in Portrait.—A little problem has presented itself on which I should be glad to have your opinion. A girl in charge of a pretty child goes into a photographer's studio to see a girl friend who is an assistant. The photographer, seeing the child, induces the nurse to allow him to photograph it there and then. The first intimation the parents have is seeing an enlargement in the photographer's window. (1) Have they any redress? (2) In the circumstances of the parents having an arrangement with a rival photographer that the child should be used exclusively as his model, would that affect the situation?—Press Operator.

(1) None under copyright law, nor, we think, under common law. (2) So far as the photographer mentioned in the first question is concerned, it makes no difference.

C.C.—(1) The efficiency of the focal-plane shutter varies according to the F. No. of the lens with which it is used and the distance of the blind from the plate, also with the width of the slit. For example, with an *f*/4.5 lens, 1½ inch slit ⅛ inch from the plate, the efficiency is 98 per cent. With the same lens and with a slit ⅛ of an inch and ¾ an inch from the plate, the efficiency is 50 per cent. Diaphragm shutters likewise vary considerably in efficiency, but never get to the 90 per cent. or so of the focal plane when used with a not too narrow slit, say one inch, and fairly close to the plate, say ¼ inch. We think you may say that the efficiency of a good average between-lens shutter is about 70 to 80 per cent., so that an exposure of 1-50th would be equal to about 1-60th or 1-70th with the focal plane at its best. There was an article on this subject in the "B.J." of March 14, 1919, page 123. (2) Chiefly by the very elaborate make-up of the cinema performers. (3) The print is a fair example of the degree of sharpness which it is possible to get in a pinhole negative. (4) Yes, it is about the correct separation of the centre of the lenses.

Halation.—I find that when photographing woodland scenery the sky and lights showing through the trees produce a halo, very pronounced, which entirely obliterates all detail where it occurs. The same thing, of course, when photographing a window in an interior. (I use films, not plates.) Are there any known means of obviating this, by the use of coloured screens or something of that kind? I find the same thing in a lesser degree in the case of pictures in sunlight where the light falls sharply and brilliantly upon an object. In such case the charm and perfection of the picture is, of course, destroyed. I have seen photographs taken by other people which do not seem to have this defect, from which fact I imagine there must be some remedy.—W. M. Belassie.

The halo (halation) is very liable to occur with subjects of the kind you mention. The use of a light-filter does a little towards obviating it, but nothing considerable. You require to apply a non-actinic backing, which can be bought from any dealer in photographic supplies, or you can purchase plates already backed. In using a backing yourself you can apply it to cut films, but the manipulation is not very convenient, and it would be best to use plates. Full exposure and unforced development has a good deal to do with obviating halation, which usually occurs in its worst form when plates are underexposed and kept for a long time in the developer.

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 3209. Vol. LXVIII. FRIDAY, NOVEMBER 4, 1921. Price Fourpence.

Contents.

SUMMARY

In a leading article we refer to the methods of intensification which are of chief everyday usefulness, in particular those with chromium and mercuric iodide, and the plan of sulphide toning the silver image. (P. 654.)

Dr. J. M. Eder sends us a contribution giving an account of a process which has been worked out in Germany for the making of dye prints from photographic negatives by the use of a sensitive coating containing benzidine hydrochloride in conjunction with a dye appropriate to the colour of print required. (P. 658.)

Dr. J. Weir French has published a valuable paper recording his experience of the various processes for silvering glass as regards the brilliance and durability of the metallic coating, and the facility for carrying out the process under ordinary conditions. (P. 656.)

In a contributed article, Thermit outlines a possible method which might be adopted for the rating of gaslight, bromide, and other development papers as regards contrast. (P. 655.)

A recent patent specification describes a method of single-solution selenium toning for red and purplish tones with development papers. (P. 659.)

An American correspondent, Mr. R. W. Harrison, of Miami, relates his experience in the successful use of hypo solution as an addition to the ordinary developer for the prevention of stress markings on development papers. (P. 663.)

A method of making studio roofs watertight, a suggestion for the two-negative method of soft-focus portraits, and the case of a visible image appearing on the plate before development are the subjects of letters from other correspondents. P. 663.)

Mr. Elwin Neame lectured and demonstrated at the Croydon Camera Club last week, when he made a strong case for the use of photography in advertising. (P. 661.)

At the Royal Photographic Society on Tuesday evening last Dr. Rodman was warmly welcomed on his appearance after his recent illness. He delivered his presidential address, in which he dealt at length with the work of Fox Talbot. P. 661.)

Fitments for extra security of dark slides and their shutters from accidental openings are described in a paragraph on page 653.

For short exposures, particularly under winter conditions of light, the small camera has very great advantages. (P. 654.)

"COLOUR PHOTOGRAPHY" SUPPLEMENT.

Particulars are contained in a recent patent specification of the device of Mr. G. Sydney Whitfield for colour registration in the Paget process when using a key screen for the making of a set of three-colour negatives from the Paget mosaic negative. (P. 41.)

Commander H. E. Rendall, in a contributed article, reviews the difficulties in the construction of a three-colour one-exposure camera, and suggests a modification of the camera patented by Walter White in 1896. (P. 43.)

EX CATHEDRA.

Overhauling Apparatus. It does not seem to occur to many photographers that the dull season, when apparatus can be spared for a day or two without inconvenience, is a suitable time for doing any repairs, adjustments or alterations which may be necessary. Moreover, the camera makers are also having their quiet time, and are able to accomplish such work more promptly than in the summer and at Christmas time, when the procrastinators are crowding them with jobs. Faulty apparatus often means a serious loss, not only in spoiled plates, but also in time and, often, in disappointing a customer. It is not possible to give a list of what points may need attention, but such things as the re-velveting of camera backs and dark slides, the repair of the flexible part of slide shutters, the adjustment of studio and hand camera shutters, and the repair of stands are frequently necessary, as the best of apparatus will not keep in condition for ever. The appearance of many studios would be improved if the camera was not only kept in working order but also in what the builders call "decorative repair." A little French polish, lacquer, and leather varnish will often make a good old camera equal in appearance to a new one at a very small outlay.

* * *

Dark-Slide Fastenings. Many photographers do not take as much trouble as they might in ensuring that the catches of their double dark slides really fulfil their purpose. Nothing is more annoying than the accidental opening of a slide or the slipping open of the shutter. The recessed turnover catches used upon the modern dark slide are quite effective as long as the slide is new, but after some wear there is a tendency for this fitting to work too easily, with the result that plates may be spoiled. If this happens, due to shrinkage of the wood or to wear, the end of the catch may be bent gently downwards with a small pair of pincers, ensuring a better grip on the woodwork. The brass only needs to be bent very slightly, and a considerable amount of care should be exercised when doing the job, or the brass may twist off where it is turned at right angles. We know one photographer who has learnt by costly experience what the accidental opening of a dark slide may mean, and now always fits his slides with a double set of catches, also fixing at the top of each slide a couple of the older pattern fasteners for additional security. The kind employed is that in the form of a brass turn button, having a recessed opening screwed to one half of the slide; when the latter is closed, this recess engages with a pin upon the other half. This precaution is of special importance to those who cycle or motor-cycle. Only a short time ago we were told by a photographer who cycled over very rough roads with a heavy field camera attached to the carrier of the machine, that the vibration was enough to unfasten two of the catches on his slides.

Small Cameras in Winter. The great depth of field which is obtained by using a very small lens at a large aperture may be turned to good account when the light is too weak for rapid exposures with a larger apparatus. Those who are unused to the vest pocket or "Blocknote" size of camera can hardly comprehend the capabilities of these little instruments with their two and a half or three inch lenses at apertures of $f/4.5$ and even larger. Some time ago in an American contemporary it was demonstrated that the depth of field at practically the same degree of sharpness was obtained by using a 6 x 4.5 cm. camera at $f/4.5$ and an ordinary 8-inch anastigmat at $f/11$ upon a 7 x 5 plate, the small negative being enlarged so that the images were identical in size. We have only to square the two f numbers to realise the decrease in exposure, which is possible by using the smaller lens. Roughly speaking, the ratio is 1 to 6. When using these small sizes it is desirable that for a given plate speed the plate having the finest grain should be selected.

THE INTENSIFICATION OF NEGATIVES.

Although the process of intensification is so frequently required, there are still many photographers who approach it with some misgiving, fearing that stains will occur and completely ruin the image. This is quite a wrong idea, since staining is not in any way inherent in any method of intensification, but is only an indication that the processes which precede it have been improperly carried out. The commonest fault is imperfect fixation, either from too short an immersion in a fresh fixing bath or from the use of an exhausted solution which leaves traces of silver in the film. The remedy is clear; if the fixing bath is in good condition the negative should be allowed to remain in it at least twice as long as it has taken to cause the visible unaltered bromide of silver to disappear. This course should be adopted with all negatives which are intended to be kept for more than a month or two, but it is essential to stainless intensification. It must not be forgotten that the ultra rapid plates now commonly used require much longer fixation than those of ordinary rapidity, and this tends to rushing the fixing process in order to make room for another batch in the dish or tank. It is advisable to keep a second fixing dish, into which plates which need intensification are transferred after they have received the usual period in the ordinary bath. As it is quite easy to see, as soon as the plate is cleared, whether it needs intensification, this extra fixation can be done before the plate is washed and dried. The next cause of stains is imperfect washing; if hypo be left in the film it will precipitate the mercury in an insoluble form, and no amount of washing will remove it. If the chromium solution be used, hypo in the film appears to reduce the image irregularly, and this is made evident upon re-development.

The most usual method of intensification is by bleaching the negative in a solution of mercuric chloride, and after well washing, blackening in a weak solution of ammonia. A considerable addition of density is obtained by this method, and if the precautions we have mentioned are taken the results should be clear and satisfactory. It is not, however, a good process for portrait negatives, as not only does it tend to the loss of detail in the highlights, but the images will certainly fade to a sickly yellow colour, it may be in a few months or in two or three years. This is a serious matter when the negative is wanted for re-orders. Fortunately, besides ammonia there are many other reagents which may be used for blackening the bleached image, and will form a more stable compound of the mercury and silver. Of these, the ferrous oxalate developer is undoubtedly the best, the results being practically permanent. Ferrous oxalate is now rarely used by the professional photographer, and recourse may be had to amidol, which we have found to answer practically as well.

Probably the most convenient intensifier for professional use is mercuric iodide; with the exception of Wellington's silver intensifier, which is too elaborate for everyday use, it is the only one which allows the degree of intensity to be controlled; moreover, it does not require very thorough removal of hypo from the film before treatment. With this the negative is immersed in a solution of mercuric iodide in iodide of potassium until the required depth is obtained, a short wash under the tap until the clear portions turn yellow, and a short immersion in a very weak, plain hypo bath until the yellowness disappears. The advantages of this method are the short time necessary and the permanence of the intensified image. In the case of a portrait sitting of four or six negatives, one or two of which require intensification, it is possible to get them into the final washing tank with the others so that the order goes through complete.

Those who distrust mercurial intensification in any form will find a perfect substitute in the chromium formula of Mr. Welborne Piper. In this the mercury solution is replaced by one containing bichromate of potash and hydrochloric acid, the bleached image being blackened by an amidol developer. This gives exceptionally clean results, and by varying the proportions of the components of the bleacher, considerable control over the ensuing density is obtained; if more density be required the process may be repeated, and the results are permanent. The chromium intensifier can be used to improve the colour and contrast of weak or bad coloured bromide prints.

Where only a small increase of density is required, it may be obtained by using the sulphide method of toning bromide prints. By this means the image is changed from black or grey to a yellowish-brown, which greatly adds to its printing power. Somewhat similar is the action of the uranium intensifier, which is, perhaps, the most effective of all for very thin negatives. With this, the increased deposit is of a deep orange-red colour, which is very non-actinic. Intensified negatives, especially those upon which mercury has been used, are very liable to show drying marks, if "tears" are allowed to remain upon the film. It is necessary to wipe the surface as dry as possible with a pad of cotton wool or soft washleather before placing them in the drying rack.

It is a common error to intensify under-exposed negatives in the hope of strengthening faint detail as the tendency of intensification is to increase contrast, it is obvious that printing must be carried on to penetrate the dense high-lights with the result of burying the shadow detail.

Flat over-exposed negatives are sometimes better for being slightly reduced with ferricyanide and hypo before intensification, but this often leaves the whole image too thin for effective treatment. If such negatives are intensified without reduction they may appear thick or muddy looking, but they will, as a rule, yield satisfactory prints with sufficient exposure.

Local intensification is sometimes desirable, and for this there is nothing better than the mercuric iodide solution, which may be applied with a swab of cotton wool where needed, washing and clearing in hypo following as usual.

We have refrained from printing formulæ, for the various solutions as these are given in the B.J. Almanac.

TESTING THE VIGOUR OF DEVELOPMENT PAPERS.

THERE is a movement afoot to induce manufacturers of development papers to express in numerals on the packets the degree of vigour possessed by the particular grade and batch of paper enclosed.

That such an innovation would be beneficial is agreed by technical workers and printers of experience. Manufacturers, however, are not unanimous as to the need for numbers, some of them arguing that the descriptions "Soft" and "Vigorous" fully cover all requirements. But printers know that confusion can exist among the numerous "Softs," Normals," "Portraits," Contrasties," etc., of which there must be over a dozen grades on the market at present, each of which is capable of giving the best from some particular type of negative, but is not the exact thing for any other type. And so we look forward to the time when all papers will be marked as having 5, 50, or 100 degrees of vigour, as the case may be. It may be admitted here that a number which correctly represented the vigour of a paper when the paper was packed would be a trifle low twelve months after, but this could be allowed for when using old stock.

With things as they are at present, it is very useful to be able to measure roughly the vigour of a paper for oneself. This can be done, of course, by printing it along with another paper that is known on a selection of negatives, but a quicker, more certain and satisfactory method is to use some kind of definite scale or wedge. I have suggested for manufacturers' use a "Vigrometer," on which a five-foot strip of paper is exposed to the rays of a 4-volt lamp, one end of the strip receiving only 1/100 of the light received by the other, the intensity of the light gradually decreasing along the whole length of the strip. A grid divides the light into 100 divisions, the records of which, on the resulting printed scale, are calculated into units of vigour. But for testing paper roughly in the printing room I employ a simpler method which I have found to be of great value at times. For example, I have known paper labelled "Soft" that appeared in use to be anything but soft. But negatives are often very deceptive, and it is not wise to blame a paper rashly. Reference to a precise method of testing puts all doubts on to a sure footing.

The simple way is to use a wedge, and the kind of wedge that I have found so serviceable is nothing more than a cleaned-off half-plate covered in layers with tissue paper. Negative envelopes opened out supplied the paper, which is clear and free from any suggestion of yellowishness. The first layer covers the glass completely, the second leaves a strip of ¼ inch in width at one end of the glass, the third leaves another similar strip at the same end, and so on. Twenty layers at the thick end will prove more than sufficient for all practical purposes.

More often than not it is convenient to test a paper by comparing it with one that is known. With the wedge in position on the printing cabinet with paper side up, a strip of each paper is laid on it, the strips reaching along the wedge so as to cover as many steps as possible. The exposure aimed at is such that, upon correct development, the first two steps of the wedge are recorded as one dead black bar on the known paper. By correct development I mean development in strict accordance with the instructions issued by the paper makers, if these agree for both papers, or by the system in use in the particular workshop, if such system is reliable and definite, or by the factorial method.

Developing out of exactly two steps is not absolutely essential, but with papers of a long exposure range—soft papers—printing out more steps may leave insufficient of the scale to fully measure the range. Printing out of the first step only is not such a definite guide to full and correct exposure, as one step alone may appear to be fully black when it is not quite so. When two steps merge it is proof that the light has penetrated the denser or more opaque to the point of full exposure.

Having fully developed the strips, if the two papers vary in vigour their relative difference will be easily seen, but first we must take into consideration their speed, which may be different. The desired result is that both scales shall be recorded somewhere between two ends of the wedge, when one end of the scale will be dead black and the other one pure white in each case. If the thin end has not been recorded fully black, the exposure has been too little, and another test must be made for that paper. If the most opaque strip of the wedge has been recorded as a decided grey, the exposure has been too great. Having found the relative parts of the wedge which print out black with the same exposure, or the different exposures which are necessary to print out the same strip of the wedge, we cannot fail to have a good idea of the relative speeds of the two papers, but that is not the object here.

The steps on the home-made wedge are not supposed to represent any recognised or previously mentioned steps in the exposure range of emulsions. Dr. Glover has stated that the deposit of a fully developed photographic image may consist of as many as 100 visible shades, and this number is a very convenient maximum for a scale of measurement. It is quite unnecessary for a scale designed for a printer's private use to be so finely divided, however, and we must not lose sight of the fact that the 100—or any other number—of steps or shades is not a limit of softness or exposure range. A scale of 100 steps or gradations could be printed on the most vigorous paper or the most soft if we had a wedge of sufficiently delicate gradation. In fact, a much longer scale might be possible with any paper if we had keen enough sight to detect all the differences.

The exposure range of a paper does not refer to the number of shades or gradations which a paper will render, but to the amount of difference between the light necessary to fully expose it, and the minimum light necessary to effect it at all. A longer range here means really a steeper range, not a range containing more gradations. Simply explained, the range might be described as a staircase, and taking the gradations of the photographic image as 100, the staircase has 100 steps. If the range is long, the steps are steep, while being equal they are high; if the range is short, the stairs are shallow or low.

The amount of light stopped by a thickness of clear white tissue such as negative envelopes are made, providing the paper is not yellowish, is about 1.5 of that which reaches it; therefore, each step in the wedge reduces the light which reaches it by that fraction, the first step passing 4/5 of the original light, the second 4/5 of 4/5, and so on. Twenty such steps will cover most papers met with in professional and commercial use.

In conclusion, I have found that an average soft bromide will record about 16 steps, a very soft one 20, while ordinary and vigorous bromides range between 14 and 5 steps respectively. An average vigorous gaslight records 5 steps, and an exceptionally vigorous one 3 to 4. Unfortunately, users' ideas of vigorous and soft papers cannot always agree with the terms as printed on the packets, where they are often misleading.

THERMIT.

WORKSHOP NOTES ON SILVERING.

[While formulæ and recipes for the silvering of glass have been freely published, there is a special value in the following paper in which Dr. James Weir French, of Messrs. Barr and Stroud, describes the result of his experience of the various silvering processes as regards the physical and optical properties of the metal coating. The paper is among those included in the volume, "The Making of Reflecting Surfaces," recently published by the Optical Society, and containing, as is pointed out on another page of this issue, a very great deal of practical information on silvering methods and also a key to the most important literature of the subject.—EDS. "B.J."]

MANY processes for the silvering of optical parts have been introduced from time to time, but the number in practical use is small. The best known processes are:—

(1) The old Mercury Tin Amalgam process.
(2) The Formaline process.
(3) The Rochelle Salt process.
(4) The Tartaric Acid process.
(5) The Brashear process.

Numerous attempts to project under vacuum fine deposits of silver upon glass surfaces have been made, and I understand that the latest information on this subject is to be placed before the meeting. There appears to be little difficulty in producing small reflectors of 1 cm. or more in diameter. Hitherto it has been very difficult to produce large, uniformly reflecting surfaces by this method.

(1) *Mercury Tin Amalgam Process.*—This process, the details of which are well known, has not been used regularly in commerce for many years, and it is now rarely used by opticians, although there are still some sea-going officers who favour it from the point of view of durability. The process has been abandoned in the industry in favour of the Rochelle salt process, because of the long time—several weeks—required for the removal of the excess mercury, and principally because of the danger to health. As the final surface contains about 20 per cent. of mercury, it is to be expected that the light-reflecting power is not good from the point of view of the optician.

There is a characteristic difference between the mercury tin amalgam and the precipitated silver in that the former cannot be used like the latter for surface silvering. The uniformity of the amalgam surface is dependent upon the polished surface of the glass with which it is in contact. The surface in contact with the glass appears highly reflecting, whereas the other side in contact with the air has a dull matt appearance. When, on the other hand, a thin layer of silver is deposited upon the polished surface of glass, both sides can be made highly reflecting.

(2) *Formaline Process.*—This process has the sole merit of being very simple and rapid, and therefore suitable for experimental work, but in the present stage of its development it is rarely used in optical manufacturing. Compared with the Brashear and Rochelle salt surfaces, the formaline surface is dark. The process has the additional disadvantage that one deposit cannot be laid upon another, and the surface cannot be electrically plated with copper.

(3) *Rochelle Salt Process.*—This process is very generally used in commerce and by opticians. It gives a brilliant reflecting surface, which, however, is about 5 per cent. or 6 per cent. less brilliant than that of the Brashear process. The difference can be detected at a single reflection. It is easily detected after three or four reflections. The process has the advantage that the silver is deposited at a normal temperature, which does not require very careful regulation.

(4) *The Tartaric Acid Process.*—So far as brilliancy is concerned, the surfaces produced by this process are nearly comparable with those of the Rochelle salt process. From the point of view of the optician, the process has the disadvantage that the best results can be obtained only when the bath is heated to about 40 deg. C. To subject finished optical parts to this temperature is undesirable. This objection is not applicable to such work as large flat mirrors, in which case steam-heated tables are used. A single deposit only is necessary.

(5) *Brashear Process.*—This process is probably the one that is most extensively used for the silvering of optical parts. It is a cold process, which gives good results at a temperature between 10 deg. C. and 20 deg. C. It is not unusually complicated, and the resulting coating is brilliant, comparatively hard, and adheres well to the surface of the glass. Coats of any thickness can be obtained by successive deposition. The layer can also be burnished for surface reflection.

Details of all the above-mentioned processes are well known. They may be obtained from any of the books of recipes, such as Spon's "Workshop Receipts." But there is one detail that cannot be too strongly emphasised, namely, thorough cleanliness, which, if neglected, will result in failure, however perfect the appliances and the methods may be.

Imperfections.

When the reflector is not near the focal plane small imperfections result only in a loss of light at the emergent pupil, and, although such a reflector may be slightly tarnished or spotted, the optical instrument may still be capable of performing its designed function.

When the silvered surface is in or near the focal plane, minute imperfections that ordinarily would be quite imperceptible may provide sufficient cause for the rejection of the instrument, especially when the power of the eye-piece is high.

Brown stains are usually attributable to impurity of the chemicals and want of cleanliness in conducting the operations and particularly the cleaning of the surface.

Pinholes in the silver which may be due to the evolution of gas bells or to the presence of dust, give rise in the course of time to systems of concentric rings which gradually broaden out. These tarnish rings have but little reflecting power, and are consequently very visible.

An unprotected silver layer on the surface of glass has very little durability. It rapidly tarnishes over the whole surface, and also is extremely liable to become spotted. It is essential that there should be as little time as possible between the silvering and protecting processes. The trouble may be due to atmospheric moisture containing acids associated with particles of dust in the air, which deposit themselves upon the silver surface. But the principal cause appears to be minute particles of saliva. From tests that have been carried out, it would appear that this substance reacts upon silver more quickly than dilute acids and alkalies. Perspiration also acts extremely rapidly on the silver, but a skilled operator exercises care in handling the silver surfaces, and is unlikely to suffer from such a source of trouble. If much time elapses between the silvering and the protecting processes, it is very difficult to prevent minute particles of saliva from landing on the surface. In one instance the number of rejections was greatly reduced by cutting out intermediate operations between the silvering and protecting operations, and thus reducing the time of exposure and the amount of handling. It will be understood that this applies to minute imperfections which under ordinary circumstances would be regarded as negligible.

Pinholes, when well defined, can be readily detected, but there is an intermediate type in which there is a local sponginess or possibly thinness of the layer. Pinholes or sponginess of this type cannot readily be protected by the electro-deposition of copper, as the pinhole in the silver will be reproduced

in the copper as a spongy or thin area. It is not sufficient, therefore, to protect the surface by means of deposited copper without an additional protection of shellac or other varnish, because the coppered surface, if left exposed to the atmosphere, will probably become affected at this point of weakness.

Cleansing of the Glass Surface.

A system that has been found satisfactory in practice when using the Brashear process is as follows:—

The surface is first cleansed with naphtha, then with nitric acid. It is fortunate that the majority of the glasses in ordinary use are unaffected by strong nitric acid. The naphtha, like most solvents, leaves a fine residual film of oil on the surface, which is not removed by the nitric acid. The surface is, therefore, again cleansed with ammonia, followed by nitric acid, and finally by distilled water. It will be understood that the cleansing process should be carried out immediately before immersing the parts in the silvering bath

When working the Rochelle salt process, after cleansing in the manner described above, the surface is immersed in a bath of stannous chloride, and then well washed in distilled water before insertion in the silvering bath. If there is delay between the stannous chloride treatment and the silvering process, the resultant coat will be unduly brown. The stannous chloride treatment appears to affect the brilliancy of the Brashear coat more than that of the Rochelle salt coat, and it is for this reason that it is not used in the Brashear process. Even in the Rochelle salt process the stannous chloride appears to have an effect upon the brilliancy of the coating. But it has the distinct advantage of producing a more adherent layer.

The action of the stannous chloride is somewhat obscure, and it would be interesting to have the opinions of the members of the Societies. I would suggest that the function of the stannous chloride is to provide a greater concentration of reducing agent directly on the surface of the glass where the deposit is desired than is obtainable from the ordinary liquids of the bath alone. It might be thought that the washing with distilled water would remove all the stannous chloride, but there is reason to believe that is not the case. After washing there appears to be an extremely thin surface film of stannous chloride, which can only be removed with some difficulty with nitric acid, but which is readily removed with hydrochloric acid.

Surface Silvering.

There are many cases in which surface silvering, either on glass or metals, would prove of great advantage, but at the present time it is hardly possible to make such surfaces sufficiently durable. It is well known that thin layers of varnish can be applied to such surfaces, the thickness of the layer when thin being so uniform as not to affect the definition under the highest magnifying powers that are customary. For example, if a drop of varnish composed of celluloid dissolved in amyl acetate and acetone is dropped centrally upon the reflector mounted upon a quickly rotating table, the varnish under centrifugal action will spread itself in a layer that is sufficiently uniform, provided it is very thin. A varnished surface of this type may appear uniformly coloured when viewed obliquely.

Experiments which the writer carried out some time ago seemed to indicate that, although the layer could be thickened without at first affecting the definition, it tended to become granular or uneven, which is intelligible in view of the enormous contraction of varnishes of this type. Surface-silvered reflectors covered with various varnishes were exposed to the atmosphere, but not directly to the weather. As the atmosphere was that of Glasgow, the test was drastic. After three months the specimens showed signs of tarnishing and spotting. It was observed, however, that in the majority of cases the bulk of the tarnishing was near the periphery, from which it appeared to spread. In a new series which was prepared, the edges were sealed with a thick layer of gum dammar varnish. After three months there was slight spotting; when examined after nine months' interval there appeared to be a progressive increase in the tarnishing and the spots had grown, but it was estimated that the total amount of tarnishing would not have reduced the illumination by more than about 10 per cent. Some time later the specimens were stolen by someone who estimated the material value more highly than the scientific.

The results of the experiments seem to show that, even when the edges are sealed, surface silvering cannot be protected sufficiently well for practical commercial use.

Reflective Power.

I had hoped to be able to give the results of a series of tests, but experiments which are in hand for the purpose of testing the absolute and relative reflecting powers of various surfaces are unfortunately not yet complete, and I can only give a few general results.

The test specimens are in the form of slips of glass about 100 mm. long and 3 mm. thick. The ends of the slip are worked to an angle of 45 deg., and the arrangement is such that the entering and exit beams are at 45 deg. to the plane of the slips. Under these circumstances the light is multiply reflected before reaching the eye, the number of reflections being the length divided by the thickness. A small imperceptible loss at a single surface becomes quite apparent after multiple reflection in this way. The amount of the loss is measured by means of a special photometer.

A mercury tin amalgam surface is generally considered to reflect at a single surface about 70 per cent. of the incident light. In this respect the mercury surface appears to be slightly better than a speculum metal surface.

Specimens silvered by the Brashear process were compared with a specimen which was photometrically tested by the German Reichsanstalt, and was certified to reflect at a single surface 98 per cent. of the incident light. The Brashear specimen was slightly superior to this German standard, and, if the German figure is accepted, it may be assumed that the Brashear surface reflects 98 per cent.

One half of a slip was silvered by the Brashear process, and the other half by the Rochelle salt process. There appears to be a difference of 6 per cent.—*i.e.*, the Rochelle salt surface reflects about 92 per cent. Another slip was similarly silvered, one half by the Brashear and the other by the tartaric acid process. The difference was 8 per cent.—*i.e.*, assuming the above value for the Brashear reflection, the tartaric acid surface reflects about 90 per cent. of the incident light.

JAMES WEIR FRENCH

STOLEN CAMERA.—Messrs. Newman and Guardia, 17-18, Bathbone Place, Oxford Street, London, W.1, ask us to mention that a new vest-pocket Baby roll film "Sibyl" camera, No. B. 1010, has been stolen from their premises. It was fitted with *f*/4.5 3-inch Cooke lens No. 102,573.

AERIAL PHOTOGRAPHY FOR ARCHÆOLOGY.—Mr. A. P. Trotter writes to "Nature," of October 28, pointing out that photographs from an aeroplane taken on a clear afternoon a little before sunset would give good records of ancient British and Roman camps, "castles," villages, rings, pack tracks, barrows, ditches, and other earthworks, and, as in such photographs taken in Mesopotamia, would probably reveal details that cannot be distinguished by inspection on the ground. Photographs might yield almost as much information as the models in the Pitt Rivers Museum at Farnham, which were made from laborious contour surveying. There are hundreds of such earthworks on Salisbury Plain, and many of them are, no doubt, related to Stonehenge and to Avebury. The stereoscopic combination of two successive photographs might disclose those parts of the banks and ditches which are nearly obliterated by the village of Avebury. General modelling is wanted rather fine detail. Perhaps such work might be done by learners.

A NEW DYE-PRINTING PROCESS.

Hitherto there have been several photographic printing processes which have been based upon the light-sensitive properties of certain dyes, in particular diazo colouring matters, which have yielded prints of generally bright colours. In diazotype process of Feer (1889), use was made of diazo sulphonate compounds which, on exposure to light, were so altered that by the action of alkaline phenols or phenylene-diamine highly-coloured compounds were obtained. In 1895 Andressen introduced a similar process in which a diazo compound of naphthylamine was employed. Both processes yield positive prints from ordinary negatives.

In the primuline process of Green, Cross and Bevan (1890) the sensitive compound was a diazo derivative of primuline, which, on exposure to light, lost its property of forming coloured compounds. In this process, therefore, a negative print is produced from an ordinary negative, a positive transparency being required for the production of positive prints. These processes have, however, not found practical application.

A process which is completely different from these earlier methods has recently been worked out by the Badische and Anilin Sodafabrik of Ludwigshafen, and has been patented in the German patent No. 337,173, of December 21, 1919. The process employs diamino benzidine bases in combination with acid dyes. The patent specification was published during the present year and good examples of the process shown.

According to the specification, the novel feature which is claimed for the process is the production of light-sensitive coatings, characterised by containing compounds of aromatic para-diamino bases with acid dyes, preferably in the presence of oxidising agents. The process is, therefore, one of photo-oxidation—assisted by the addition of salts containing oxygen, such as nitrates, chlorates, etc. The time of exposure is long, about four hours, and the process allows of making prints in a wide range of bright colours, red, purple, green, bluish-black, browns, etc.

The process for the preparation of the light-sensitive diamine coating is divided into two operations: (1) Benzidine hydrochloride or other diamine compound is precipitated with an acid dye, such as eosine, cyananthrol, Neptune green or quinoline yellow. (2) This precipitate, which must contain the free benzidine base.

$$NH_2\text{-}C_6H_4\text{-}C_6H_4\text{-}NH_2$$

is decomposed with manganese nitrate, calcium, nickel or magnesium nitrate, picric acid or similar oxidising agent and coated on glass or other support by means of a colloid medium, such as gelatine or albumen.

Fixing is done by treatment in a weak alkaline solution, such as borax or sodium phosphate.

Modification of the bright colours may be made by after-treatment of the prints in a very dilute solution of sodium hypochlorite, or with a 1 per cent. bichromate solution.

A number of prints sent to the writer by the Badische Anilin und Sodafabrik consist of exceedingly bright red, green, blue and brown paper prints (of landscape and architectural subjects), which exhibit good gradation of light and shade, and possess satisfactory permanence. Up to the present, however, it has not been possible to obtain pure high-lights.

The following are formulæ for the preparation of the sensitive coatings:—

A.—Bright Purplish-Red Prints.

Blanc fixe paste (30 per cent.)	100 parts.
Anhydrous soda carbonate	10 ,,
Fish glue (20 per cent. solution)...	15 ,,
Eosine A.	20 ,,
Benzidine hydrochloride (2 per cent. solution)	800 ,,

By treatment of the finished prints with a weak solution of hypochlorite the colour is rendered a brighter red.

B.—Dark Violet Prints.

The formula is the same as A, except that 20 parts of cyananthrol R.B.X. are used instead of the eosine and 850 instead of 800 parts of the benzidine hydrochloride. By treatment of these prints with weak hypochlorite solution the colour is converted into a good sepia brown with a slight reddish shade.

C.—Bright Green Prints.

The formula is the same as A, but is compounded with 20 parts of Neptune green S.G.X. in place of the eosine. The bright green colour is converted into a much more pleasing dark green by a weak solution of hypochlorite.

D—Brown Prints.

By the use of 20 parts of quinoline yellow L extra and 700 parts benzidine hydrochloride solution, prints of brownish colour are obtained. In other respects the formula is the same as A, the quinoline yellow taking the place of the eosine.

The preparations A to D mentioned above are mixed with 40 parts manganese nitrate and 40 parts of water, and are coated on paper, dried, exposed under the negatives and fixed in a solution of borax or sodium phosphate in water.

The process is of considerable scientific interest, although its practical value is discounted by the fact that so far prints having pure whites cannot be obtained. The great brilliance and variety of the colours and the gradation and vigour of the prints are very marked in the specimens, so that it may be considered that the process is worthy of attention.

J. M. Eder.

Art of Studio Lighting.—Under the auspices of Messrs. Kodak, Ltd., a most instructive and interesting lecture and demonstration in "The Art of Lighting in the Studio," was given by Mr. Luboshez to the professional photographers in Edinburgh and district, on Tuesday evening in last week. Messrs. W. and E. Drummond Young, 12a, Frederick Street, Edinburgh, kindly placed their studio at the disposal of the lecturer for the evening. There was a large attendance of professional photographers from Edinburgh and provincial towns.

Mr. Luboshez illustrated the methods of lighting used by the old masters, especially Van Dyck and Rembrandt. He carefully demonstrated how to light the model first on the front top light, as generally used by these masters, and showed the safety of using such lighting. He pointed out how the high-lights on brow, nose, cheeks and chin were correctly shown, the ear and back of the head falling into shadow without screening or help from the operator. In demonstrating the top side light Mr. Luboshez pointed out the defects of side light when uncontrolled. The ear being nearest the light became too prominent, and the necessary screening was done to correct this and fully explained by Mr. Luboshez in a delightful and entertaining manner. The so-called Rembrandt, top, double, cinema and stage lighting were demonstrated, and films exposed and developed.

Mr. Luboshez explained the use and qualities of various electric lighting systems, and spoke in laudatory terms of Messrs. Drummond Young's system.

Mr. Campbell Harper, the President of the Edinburgh Society of Professional Photographers, in moving a vote of thanks to Mr. Luboshez, expressed the gratitude of the company present to Messrs. Kodak, Ltd., for sending Mr. Luboshez to Edinburgh to deliver the lecture. He also moved that a hearty vote of thanks be given to Messrs. W. and E. Drummond Young and their staff for the use of their studio and electric light for the lecture. Mr. Luboshez and Mr. E. Drummond Young suitably replied.

Patent News.

Process patents—applications and specifications—are treated in "Photo-Mechanical Notes."

Applications, October 17 to 22 :—

CAMERAS.—No. 27,641. Photographic cameras. W. Atterton and W. Loveless.

FOCUSSING-DEVICE.—No. 27,530. Focussing-means for photographic cameras. E. F. Stratton.

CAMERAS.—No. 27,796. Photographic cameras. A. Veacock.

COLOUR CINEMATOGRAPHY.—No. 27,686. Apparatus for production of projected pictures in natural colours. E. H. Tarlton.

COMPLETE SPECIFICATIONS ACCEPTED.

These specifications are obtainable, price 1/- each, post free, from the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C.

The date in brackets is that of application in this country; or abroad, in the case of patents granted under the International Convention.

PAGET COLOUR PROCESS.—No. 167,793 (February 20, 1920). The invention consists in an addition to the taking screen used in the Paget process, namely, of two strips of different colours, each of which is transparent to the light passed by two different pairs of the colour elements in the screen. For example, one strip may be greenish-blue, transmitting light which is passed by the green and blue-violet units of the screen, whilst the other is yellow, transmitting light which is passed by the red and green elements of the taking screen. This device provides a colour indication of the correct registration of a stop-out or key screen with the negative made through the taking screen, when preparing negatives which shall be records of a single colour sensation.—G. Sydney Whitfield, The Paget Prize Plate Co., St. Albans Road, Watford, Herts. (Further particulars of the principle and use of this device will be found upon another page in the "Colour Photography" Supplement.

CINEMATOGRAPH LANTERN SCREENS.—No. 159,851 (March 1, 1920). The invention consists in a screen which may be employed for projection in daylight, and for that purpose has a coating

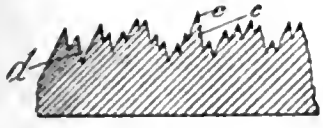

Fig. 1

Fig. 2.

Fig. 3

which absorbs the diffused general illumination, while reflecting that from the projection lantern.

The coating may be applied in a mechanical or in a chemical way. In many cases it will be advisable to effect the coating

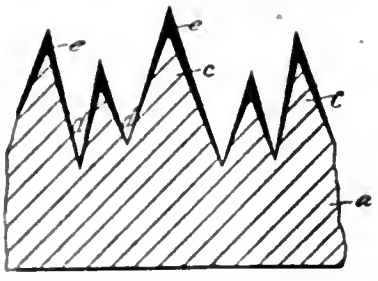

Fig. 4.

of that surface of the screen which is directed towards the spectator by providing the surface with a dark-coloured layer of glass, gelatine, glue, or some other suitable material or substance, and to perforate this layer in a great many places by means of a sand blast or by etching, so that in the deeper portions of the perforations the transparent surface is laid bare in a great number of places.

In the drawings, *a* is a portion of a projection screen in which the surface on the side facing the spectator is roughened in known manner so as to form projections *c* and recesses *d*. According to the constructions shown in figs. 1—3 only the tips of the projections are coloured with a dark colouring *e* capable of absorbing the light and covering the sides and the edges of the projection points.

If desired, the coating *e* may be continued in decreasing magnitude right into the recesses *d*, as shown in fig. 4.

A special way of applying the coating is shown in fig. 5, in which the surface of the projection screen *a* is provided with a layer *b*. The latter is irregularly perforated, as by means of a sand blast, etching, or the like, so that in the deeper portions *f* of these perforations *g* the transparent surface *a* of the projection screen is laid bare in a great number of places.

The mode of operation of the invention is that the daylight falling on to the screen will not be reflected by the darkened

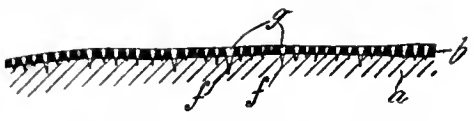

Fig. 5.

tips, but will be absorbed, whilst the image produced by the projection apparatus passes unaffected through the uncovered, or only lightly covered, recesses in the roughened or net-like surface.—John Emlington-Darling, 5, Culmbacher Strasse, Wilmersdorf, Berlin, assignee of Carl Oskar Roehrich, 4, Augsburger Strasse, Charlottenburg, Berlin.

SELENIUM TONING.—No. 169,378 (September 7, 1920). Baths which contain selenium in an alkaline solution for toning photographic papers are well known. These baths have the disadvantage that they have a corrosive effect on the fingers of the operator, and that they affect the gelatine on the paper, which causes the colouration of the emulsion side, or even of the rear side, of the paper.

Means have now been found to obviate these disadvantages. It has been discovered that these alkaline baths can be diluted with boric acid without precipitating the selenium. The baths thus treated will no longer have a corrosive effect on the human skin, and will no longer affect the gelatine on the paper. Reddish tones are obtained with facility, as is usual with selenium toning.

Completely fixed and washed images made on developing paper, which may be placed in the bath whilst damp or after drying, receive within a short time the pronounced reddish-brown tone.

Images made on printing-out paper are preferably treated with a solution which is 20-30 times as dilute as that for prints made on developing paper. Within a short time purple tones are also obtained similar to those obtained with gold toning baths.

The whites are frequently easily coloured with such baths. This can be avoided if ammonia or sodium sulphate is added to the bath.

The following baths are recommended for prints on dovelopment papers :—

(1) Solution 100 gms. soda sulphide and 10 gms. selenium in 500 c.c.s. water ...	20	c.c.s.
Water	220	c.c.s.
Ammonia, 25% solution	40	c.c.s.
Boric acid, 1 : 29 solution	20	c.c.s.

Prints should be cleared after toning in a 10% solution of potassium metabisulphite.

(2) Solution of 100 gms. sodium sulphide and 10 gms. selenium in 500 c.c.s. of water...	20	c.c.s.
Sodium sulphate, 1 : 6 solution	220	c.c.s.
Boric acid, 1 : 29 solution	20	c.c.s.

With this bath it is not absolutely necessary to employ the metabisulphite clearing bath. Both baths tone in about two minutes.—Mimosa Aktiengesellschaft and Dr. Felix Formstecher, both of 31, Bärensteiner Strasse, Dresden.

The following complete specifications are open to public inspection before acceptance :—

PROCESS SCREEN.—No. 170,270. Photo-process screen and method of preparing the same. J. A. H. Hatt.

COLOUR CINEMATOGRAPHY.—No. 170,267. Optical system for a three-colour exposure cinematograph. Firm of C. Zeiss.

Trade Names and Marks.

APPLICATIONS FOR REGISTRATION.

KOTINIC.—No. 418,037. Flashlight powders and other preparations for flashlight purposes, all being for use in photography. Kodak, Ltd., Kodak House, Kingsway, London, W.C.2, dealers in photographic materials. August 27, 1921.

SALEX.—No. 417,493. Photographic apparatus included in Class 8. Richard Green, trading as The City Sale and Exchange, 81, Aldersgate Street, London, E.C.1, merchant. August 6, 1921.

OMEGA.—No. 418,011. Cinema projection lenses. L. Le Personne & Co., 99, Cannon Street, London, E.C.4, merchants. August 26, 1921.

KALO.—No. 418,129. Photographic paper, photographic albums, and photographic mounts included in Class 39. Ilford, Ltd., Britannia Works, Roden Street, Ilford, Essex, manufacturers of photographic plates, papers and films. August 31, 1921.

IKO.—No. 418,228. Photographic paper, photographic albums, and photographic mounts, included in Class 39. Ilford, Ltd., Britannia Works, Roden Street, Ilford, Essex, manufacturers of photographic plates, papers and films. September 2, 1921.

MARKS PLACED ON THE REGISTER.

The following marks have been placed on the register:—

DUPLI-TIZED.—No. 416,805. Photographic films. Kodak, Ltd., Kodak House, Kingsway, London, W.C.2, dealers in photographic materials.

FORTHCOMING EXHIBITIONS.

November 17 to 19.—Bowes Park and District Photographic Society. Particulars from the Hon. Sec., S. Smith, 68, Mannock Road, Wood Green, London, N.22.

November 23 to 26.—Rotherham Photographic Society. Latest date for entries, November 9. Particulars and entry forms from the Hon. Exhibition Secretary, Sydney G. Liversidge, "Orissa," Gerard Road, Rotherham.

December 3 to 17.—Scottish Photographic Circle. Hon. Secretary, W. S. Crocket, 10, Parkgrove Terrace, Tollcross, Glasgow.

1922.

January 21 to February 4.—Partick Camera Club. Latest date for entries, January 30. Particulars from the Hon. Secretary, James Whyte, 51a, Peel Street, Partick Glasgow.

February 14 to 17.—Exeter Camera Club. Particulars from C. Beauchamp Hall, Hon. Exhibition Secretary, Exeter Camera Club, "St. Denys," Bellevue Road, Exmouth.

February 11 to 25.—Scottish Photographic Salon. Particulars from the Secretary, James F. Smellie, Braefindon, Allanshaw Street, Hamilton.

A REMINDER OF CHRISTMAS TRADE.—Those photographers who make a special bid for the photographic Christmas card trade would do well to bear in mind the following dates, which are the latest for the despatch of Christmas letters and parcels to soldiers serving abroad:—Rhine, letters, December 20, parcels, December 15; Black Sea, letters, December 10, parcels, middle November; Egypt and Palestine, letters, December 8, parcels, November 29; Mesopotamia, letters, November 17 or 24, parcels, November 8; India, letters, December 1, parcels, November 15.

PORTRAITS AS ADVERTISEMENTS.—The death last week of Mr. J. B. Dunlop, of pneumatic tyre fame, recalls the famous action concerning the use of his photograph for the purposes of advertisement. It may be remembered that in 1891 he presented a signed portrait bust of himself to the tyre company to be used as a trade mark. This was later developed into a figure which became familiar in advertisements. But last year he brought an action for libel against the Dunlop Company, complaining that he had been misrepresented as "a very tall man dressed in an exaggerated foppish manner, wearing tall white hat, a white waistcoat, and carrying a cane and eyeglass, none of which it was his custom to wear or carry." He said this had caused him very great annoyance in Dublin, where he lived, and eventually the company consented to discontinue the publication of the picture in Ireland.

New Books.

The Making of Reflecting Surfaces. Papers read at a Joint Meeting of the Physical and Optical Societies. 5s.

A CONSIDERABLE service has been rendered to those having occasion to undertake the silvering and platinizing of glass in the publication, in separate form, of the series of papers read at a joint-meeting of the Physical Society of London and the Optical Society, in November of last year. The present volume is a symposium, from the current standpoint, of the practice and literature relating to the coating of glass and other substances with a reflecting metal surface, and, moreover, includes within its scope the making and use of metal mirrors. There are thirteen papers in the volume, including the survey of the bibliography of metallic deposition on glass, by Mr. R. Kanthack and the chronological list, by the same writer, of the chief papers and publications dealing with the technics of the subject. It is interesting to note that the photographic journals of the second half of the last century were the places of first publication of a considerable number of the processes of silvering glass, and the "British Journal" and the "British Journal Almanac" figure prominently among them. Mr. Kanthack's list of evidently an exceedingly valuable guide to the scattered literature of silvering and platinizing. The communications include a paper on workshop experience with silvering processes by Dr. J. W. French, which we reprint on another page. Messrs. F. Ellerman and H. D. Babcock, of the Mount Wilson University, give practical details of silvering large glass reflectors, and Mr. C. R. Davidson, of the Royal Observatory, Greenwich, in like manner contributes his experience. A very full account is also given by Mr. Julius Rheinberg of the process of platinizing by the burning-in process devised by him. Some further brief contributions deal with the use of mirrors in optical instruments under industrial conditions, and with a method of measuring the aggegate reflecting power of mirrors. In the former it is mentioned that a mirror of stainless steel was found to reflect 68 per cent. of light, an efficiency which is pretty good in comparison with a silver surface, and suggests the practicability of employing such mirrors in reflex cameras and for other photographic instruments. It will be remembered that many years ago Abney employed steel mirrors in three-colour cameras. The great amount of information brought together in the present monograph will, we are sure, be appreciated by opticians and others. The volume may be obtained from the Optical Society, Imperial College of Science and Technology, South Kensington, London, S.W.7, price 5s. 3d., post free.

ROYAL PHOTOGRAPHIC SOCIETY.

Meeting held Tuesday, November 1, Mr. F. F. Renwick in the chair.

The President, Dr. G. H. Rodman, who was present against his doctor's orders, was cordially received on rising to deliver his presidential address. He referred at the outset to evidences of the continued activities of the Society during the past year, particularly in the progressive increase of membership and on the support accorded to other societies, such as those interested in radiography and photo-micrography.

He touched upon pictorial photography, and while commending the objects of the Pictorial Group, expressed the belief that the future of pictorial work with the camera lay with the fuller utilisation of the capabilities of present-day lenses and colour-sensitive plates. He pointed to works of J. M. Whitehead and Fredk. H. Evans in pure photography as examples of artistic achievement which had a permanent value. He was unable to do as much for much of the highly "controlled" photography which was produced by methods such as Bromoil.

He then turned to pass in review the discoveries which might be said to be included in "the invention of photography." On the optical side, the formation of a lens image of an object, the foundation was laid in the cameras of Barbaro and Porta in the sixteenth century. On the chemical side, the fixation of the optical image by the action of light, the work of many investigators had led up to practicable photographic processes. Dr. Rodman rapidly traced the successive labours of Schulze, Scheele, Wedgwood, Niépce, Reade, Bayard, Herschel and Daguerre, and, in greater detail, of Fox Talbot. Alluding to the bequest to the Society of apparatus of Fox Talbot and examples of his earliest results, by his granddaughter, he showed early and later portraits and many interesting ancient and modern photographs illustrating Fox Talbot's work and home at Lacock. A collection of the apparatus and other relics was on view. Dr. Rodman also referred to the fund now being raised to establish a memorial to Fox Talbot, and showed a photograph of the interior of Lacock Church, where it was possible that a window might be placed in commemoration of the experimenter. He urged that contributions to the fund should be forthcoming in order that long-delayed public recognition of Talbot's investigations might be adequately made.

Tracing the later development of photography through the wet-collodion and dry-plate eras, the President referred to the immense popularity conferred by the introduction of daylight-loading film and cameras by the Eastman Company, and concluded by contrasting examples of a vest-pocket Kodak and a Sibyl camera with the primitive and cumbrous apparatus of the early days.

On the proposition of Mr. E. W. Mellor, seconded by Mr. T. H. B. Scott, the hearty thanks of the meeting were accorded to the President for his address.

CROYDON CAMERA CLUB.

A fixture which proved one of the "very best" was provided last week by Mr. Elwin Neame, who lectured on "Photography in Advertising." The walls were covered with photographs illustrating the subject, most of the highest technical excellence and alluring charm, even if they did not bow to the canons of Fine Art, but undeniably clever nevertheless.

A stately and very attractive young lady accompanied the lecturer, and adopted various elegant poses when requested. In the long intervals of rest, a member (who had celebrated a silver wedding) having crossed the room and secured the next chair for the purpose, chatted paternally, amiably, and continuously with the fair visitor, resisting with great skill all attempts at dislodgment. Even the president, gifted on similar lines, hardly had a look in, and the rest were absolutely nowhere. The gay young Lothario is gently reminded that men have been killed in cold blood for less than this.

Mr. Neame first narrated his early experiences in photography, which began with a guinea hand-camera fitted with a "rebound" shutter of a highly energetic description. Next came a 70s. field outfit with real leather bellows, R.R. lens, and one D.D. slide complete. An art school followed, which in itself was all right, but art money appeared to languish, so he plunged for photography, and after operating for two years started on his own. Things went well following much hard work, but down in the bottom of his unconscious soul lay a latent ambition, unidentified and therefore incapable of realisation. Only when he remembered quite recently that he had never visited the Croydon Club did the inconcrete become concrete, and he immediately called on Mr. Geo. E. Brown who, after pointing out the peril of the adventure, put him into communication with Mr. Sellors.

He was out for propaganda, for photography is the best of all mediums for advertising, and Neame, he said, is undoubtedly the man for the job. (This modest statement was certainly made good during the evening.) In America photography is far more widely used for advertising than in this country, but an ever-increasing and remunerative business is now being done here. The general public usually suspects a line drawing, but knowing "the camera cannot lie" accept its evidence unquestioningly. Also, many buyers for commercial houses will not look at a sketch which is apt to let them down, but will transact business on the strength of a photograph.

The great difficulty is to know what is required, and the first thing to do is to ask the customer "What is your kink?" for the special characteristics, whether of a corset or motor-car, must be emphasised, and first-rate technique and quick delivery are compulsory adjuncts to success.

Unfortunately, some customers have but hazy ideas what they do want, and this frequently adds greatly to the difficulties of advertisement work. As regards costumes worn by models, the conditions necessitated a fairly quick exposure, and the necessity of securing fine detail a medium stop. In such cases screened orthochromatic or panchromatic plates are not easy to work, but by judicious arrangement with the makers, characteristic costumes presenting suitable colour-contrasts for a fast "ordinary" brand may be found. As a general rule the print must be vigorous, with a bold note of outline, lighting, and gradation.

The foregoing gives the salient points mentioned by Mr. Neame. What he did not allude to, but what was very evident, is that he is possessed of a fertile and inventive brain which devises photographs which admirably advertise goods of all descriptions. This ingenious method of introducing "natural" backgrounds (published some time ago) is undoubtedly a powerful aid to success in many cases, as it forms a rather theatrical setting in harmony with a scheme which has to be assertive. Back lighting is another powerful factor towards the same end in studio work.

He often employs 24,000 candle-power behind the sitter, and only 4,000 c.p. in front. Half-watt lamps are used, and the lens, of course, is carefully shielded from direct rays.

The rest of the lecture was devoted to some really valuable hints on posing, and to the consideration of art maxims. For instance, Δ = stability: the "S-curve" = beauty, and so forth, the maxims being fascinatingly humanised by the young lady, the Δ excepted. In the discussion, Mr. Catharine, who is an engineer familiar with heavy pressures, chatted pleasantly on corsets, and was followed by a long string of questions from other members. In reply to one query, the lecturer said the best print for reproduction was one on P.O.P. toned to a purple-blue without suspicion of double-toning. A most hearty vote of thanks was accorded Mr. Neame, and the young lady assisting, with much acclamation. Societies that can prevail upon him to name an evening will ensure a fixture of outstanding interest.

News and Notes.

Mr. George J. Hughes, Waterford, Ireland, sends us a reply envelope to a recent advertisement of his in the "B.J." which has reached him without contents. His correspondent, who, it is thought, wrote from Bolton, is asked to address him again.

Death of Mr. S. G. Downing.—We much regret to announce the death, which took place at Highgate last week, of Mr. S. G. Downing, who for some years past has been manager of Messrs. Wellington & Ward's branch at Bombay. He only returned from India about three weeks ago and succumbed after a very short illness.

Focussing Screens.—A correspondent of the "Club Photographer" points out that the Barnet matt-emulsion plate, when fixed out and washed, makes a superb focussing screen. Although Messrs. Elliott term their product a "self-screen" and not "focussing screen" plate, it cannot be denied that an article that lends itself to uses other than those for which it was designed is a decided acquisition.

Houghtons' "Professional Bulletin" for October contains an article by Mr. Marcus Adams in appreciation of Mr. Pirie Macdonald and in advocacy of a matter of which we have often urged the desirability, namely, the making and entering of prints for exhibitions. The issue contains descriptions of Messrs. Houghtons' latest items for professionals, among them embossed mottoes for sticking on Christmas photographs and a new Father Christmas studio accessory.

Sheffield and District Professional Photographers' Association.—A well-attended meeting of the Society was held on Wednesday, October 26, at Miss Eadon's Studio, when Mr. G. Henderson, of the Imperial Dry Plate Company, showed the working of their new Eclipse Plate, 600 H. and D., its characteristics and its use for short exposures and electric light portraits. A vote of thanks to the demonstrator, to Miss Eadon for the use of her studio, and to Mrs. Hinkin for her service as model brought a very interesting evening to a close.

Smiling Poses Unfashionable.—A writer of Society gossip paragraphs in one of the evening papers (the "Star") states that "The day of the smiling beauty anxious to display a fine row of teeth is done. Society girls and stage celebrities have all adopted the more than serious expression; indeed, it seems quite the thing to look a trifle sulky. But, of course, when a whim of this kind is sponsored by such an undisputed beauty as Gladys Cooper, lesser fry are bound to take it up both in stage and Society circles. Only the result is not always so artistic. Apparently the idea is to look as though you are being 'taken' against your will."

The Scientific American.—The first issue of our contemporary in its new monthly form, incorporating the "Scientific American Supplement," is a handsome magazine covering a wide field of technics and science. The present issue contains illustrated contributions on such varied subjects as bridge building, the evolution of the Dreadnought, safety of aeroplanes, wireless telephony, super-range artillery, mountain tunnelling, to name only a few of the headings of its many pages. There are also some notes on the desensitising of photographic plates, and a series of drawings illustrating the 16 stages in the making of the offset plate by which the coloured cover is printed. In its new form the magazine is published at 35 cents a copy, 4 dollars per annum, in the United States. Foreign subscriptions, 5 dollars per annum.

Society Programmes.—The lists of fixtures arranged by photographic societies in this country look poor things beside those of some which we receive; for example, of the California Camera Club, kindly sent to us by the secretary, Mr. W. Mackintosh, of San Francisco. Among the fixtures for last month is a whole-day water excursion to Paradise Park in San Francisco Bay, where there is a beach and a dancing pavilion. Members are entreated to bring their bathing suits and a big lunch. But even this fixture appears tame beside the arrangements for a Halloween costume party on October 28, when "witches and owls, pumpkins and jack-o-lanterns will be much in evidence."

Manchester Amateur Photographic Society.—The annual exhibition is being held at 5, Carr Street, Blackfriars, from to-morrow, Saturday, November 5 to November 12, from 5.30 to 10 p.m. During the period of the exhibition the following lectures will be given:—November 5, "Charm of the Hills," W. W. F. Pullen; November 7, "Derbyshire Dales," J. B. Berwick; November 8, "In and Around St. Paul's," E. W. Harvey Piper; November 9, "Glimpses into Nature's Secrets," Fred Taylor; November 10, "Some Dravidian Landmarks of Southern India," E. W. Mellor; November 11, "In the Shires of the Sea Kings," Rev. S. R. Laundy; November 12, "Burgos and a Bull Fight," James Shaw.

Diplomas in Radiography.—The establishment of a diploma in medical radiology and electrology by the University of Cambridge (writes "Nature") was made at the instigation of the British Association for the Advancement of Radiology and Physiotherapy (B.A.R.P.). This association has also been instrumental in forming a Society of Radiographers, having as its object the consolidation of the position and improvement of the status of the lay assistant who carries out the routine work at hospitals under the direction of the medical head of the department. The Council of the Society of Radiographers has arranged for an examination to be held yearly, and instruction for this examination is being greatly facilitated by the co-operation of the Institution of Electrical Engineers. Successful candidates will be entitled to use the letters M.S.R. These dual activities of the B.A.R.P. are a good augury of the desire among radiologists to improve the status of medical work involving the use of the various forms of electricity and radiation.

Correspondence.

STRESS MARKS ON DEVELOPMENT PAPERS.

To the Editors.

Gentlemen,—I am often inclined to write on subjects mentioned in the "B.J.", but my "frame of observation" being so different to yours, and my means of communication so slow, I fear a difference in my dimensions, especially the fourth. (With apologies to Einstein.) But there is a point on which I think I can make a suggestion of real value, even if it is a month behind time.

On page 592 in the "Answers" I take it that a correspondent is troubled with stress marks on glossy paper. We call them abrasion marks on this side of the herring pond, because we find that the marks can be made by any rubbing which abrades the surface. About two years ago some of my Velvet Velox paper showed these marks, so that I was obliged to give it up and use another make. My foreman is a dyed-in-the-wool Velox man, and often complained of the inferiority of this latter paper. About a year ago he asked me to send in a small order for Velox, and see if it was any better. So I ordered a few thousand sheets, and we found it worse than ever. We knew that iodide of potassium in the developer would prevent the marks, but we also knew that it

would shorten the efficiency of the developer to about one-half and degrade the quality of the work. So it was ruled out; better use a slightly inferior paper than a much inferior developer. At last he suggested that I try to find something better than iodide. I tried a number of things which I thought might work, mainly at first with the purpose of modifying the iodide and preventing its deleterious action, but all were failures.

In working out photo-chemical problems in late years, if they do not solve by probable methods I reverse my tactics and begin with what I consider the most improbable.

It has been a lifelong habit, religiously observed for nearly a half-century, when I use hypo to wash my hands before touching even a towel. When I was asked why, among other reasons given was "you might get some in your developer." So I defied my bugaboo of forty-seven years' standing, and *put* hypo in my developer, cautiously at first, but with increasing temerity as results encouraged. The idea was to prevent the iodide from doing harm, but I soon found that with hypo I did not need as much iodide. This led to leaving out the iodide and using hypo alone. So I handed the foreman a solution, and asked him to try it out in the printing room, and see how it affected the prints and the effectiveness of the developer. He reported that he could see no difference in the prints, except that there were no abrasion marks, and the developer stood as well as any he had ever used. Under-exposed prints would be slightly yellow, but a print that was much under-exposed would in any case be unfit to pass according to our standards.

It has been my experience that a fragmentary suggestion like this rarely works out under different circumstances than those in which it was first successful; so I think it best to give my whole practice in this matter.

A few years ago I told in the "B.J." my objections to stock solutions of developer, so I will now re-state the method of procedure in my printing room. On the mixing shelf there is a tin which holds about two quarts. In this is Elon and hydroquinone 1 to 4 by weight dry. A small tin cover stays with this tin, and measures the amount of the dry crystals needed for a quart (32 ounces) of developer. Beside that is a larger tin containing anhydrous sulphite and carbonate of soda, equal parts by weight, and a measure required for the amount used in a quart.

The printer takes a quart of distilled water, adds the proper measure of dry elon-hydro, and stirs a little, then adds the proper measure of sodas and stirs vigorously, adds 7 drams of a 10 per cent. solution of potass bromide, and 4 drams of a 10 per cent. solution of sodium thiosulphate (hypo), and in the time it takes to read it absolutely fresh developer is ready for use. We use our developer at or near 65 Fah., which means with us ice about 300 days in the year, and we never use a solution kept over night.

So with the addition of hypo to the developer we began again to use Velox, and never had a stress or abrasion mark all winter, although our output was from 4,000 to 6,000 per day. The hypo solution was known in the printing room as "non-abrasion dope," and recently I asked the foreman if any of the printers had tried to find out what it was, and he said that not one had shown the slightest curiosity. Men are queer cattle.

R. W. HARRISON.

Studio of Photographic Art, Miami, Fla.

WATERTIGHT STUDIO ROOFS.

To the Editors.

Gentlemen,—I see your correspondent, "M. W.," is, like a large majority of fellow-photographers, troubled with a leaky roof. If he cares to try the following experiment I think he will find his trouble at an end:—

Procure a quantity of the purest linen and some of the best oil paint (colour is of no consequence), cut the linen into strips of 3 ins. wide and the length of the sash bars, now give the bar and glass around it a good coat of the paint, and lay the strip of linen on to it, and rub well down with a cloth, and apply another good coat of paint on the top. When this is thoroughly dry I think it will withstand anything.—Yours faithfully, V. L. WYBALL.

Gipsy Hill, London, S.E.19.
October 28.

DESENSITIZING WITH POTASS IODIDE: FREUND'S PROCESS.

To the Editors.

Gentlemen,—In reply to the letter in your columns from Mr. Bolas dealing with our recent article on "Freund's Method of Desensitizing Dry Plates," we beg to assure him that we have no desire to appear as "skilled dialecticians," but simply as students of photographic science willing to learn from anyone who has something new to bring forward.

We are reluctantly driven to the conclusion, from a careful reading of his letter, that Mr. Bolas has no new facts to offer on the subject, and we do not, therefore, propose to send him even the reply postcards he suggests.—Yours faithfully,

Ilford, E. November 1. O. F. BLOCK.
F. F. RENWICK.

VISIBLE IMAGE ON DRY-PLATE BEFORE DEVELOPING.

To the Editors.

Gentlemen,—While washing backing off a 12 x 10 plate of a flash-light group, prior to developing, I was surprised to find that the figures in the group had already appeared on the film and were quite distinct. The negative was a little under-exposed, quite clear and free from fog. The plate was a Wellington studio anti-screen. People I have spoken to consider this a very unusual occurrence.—Yours truly, H. W. LEVERTON.

112, Peckham Rye, S.E.15. October 31.

CAMPHOR IN THE CAMERA CASE.

To the Editors.

Gentlemen,—With reference to the inquiry regarding the effects of keeping camphor, etc., in the camera case, I may say that for over 30 years I have kept a piece of camphor in my case, and, though plates in many instances have remained in the slides for many months, no ill effects have resulted from it. Camphor has also always been kept in the print drawers. I would not care to recommend naphthalene, however, for similar use.—Yours faithfully,

W. J. BARKER.

14, Victoria Mount, Woodsley Road, Leeds. October 29.

ARTIGUE'S TWO-NEGATIVES METHOD FOR SOFT FOCUS PORTRAITS.

To the Editors.

Gentlemen,—As the front plate has to be over-exposed in order to sufficiently expose the rear plate, I suggest the slower flat film should be used in front instead of a plate which cannot be backed. I intended trying this, and should have written last week but have not had opportunity to do so.

I fancy with light drapery and light backgrounds there would otherwise be more halation on the front plate than desirable, although a slow plate in front should mitigate it. The film could, if necessary, be slightly separated from rear plate by another plain film.—Yours truly, WILLIAM COLES.

16, Queens Road, Watford. November 1.

Commercial & Legal Intelligence.

NEW COMPANIES.

FILM FACE FOTOS, LTD.—This private company was registered on October 20. Capital £2,000 in £1 shares. Objects: To take over the business of Williams & Da Silva, and to carry on the business of photographers, artists, colourmen, dealers in works of art, managers, and proprietors of studios, etc. The permanent directors are: E. T. Williams, Lawrence House, St. Margaret's, Middlesex; L. D. Da Silva, 5, Effingham Street, S.W.1; J. Wright, 149, Brixton Hill, S.W.2. The two first-named are joint-managing directors. Qualification of ordinary directors: £250. Secretary: J. Wright. Registered office: 32, Shaftesbury Avenue, W.1.

Answers to Correspondents.

In accordance with our present practice a relatively small space is allotted in each issue to replies to correspondents.

We will answer by post if stamped and addressed envelope is enclosed for reply: 5-cent International Coupon, from readers abroad.

Queries to be answered in the Friday's "Journal" must reach us not later than Tuesday (posted Monday), and should be addressed to the Editors.

N. U. R. (London).—Conditions are none too good at the present time, but they show signs of improving, and there is always business to be had by retouchers who can do really first-class work.

Caterham.—The article by Mr. John H. Gear on the D.50 developer appeared in our issue of May 27 last. The developer is manufactured and sold by the Cooper Research Laboratory, Watford, Herts.

K.B.—The mixture referred to is probably that of Stockholm tar and linseed oil putty in equal proportions. There are several preparations now sold for stopping leaks in ordinary roofs which might be useful in this case. One is called Matex, and another Farotex. These are very adhesive and do not set hard.

Axiom.—(1) We do not know of any method of dry development that is an improvement on the Douglasgraph method, published in the "B.J." of August 27, September 3, 1920. The bichromate gum film, when dry, is very sensitive to direct daylight, and—even indirect rays of the enclosed arc lamp. Should those rays strike the film it is impossible to develop a clean stencil, the result being that the ink will not adhere to the metal. (2) 4 to 5 per cent. for enclosed arc lamp. (3) We do not know of any.

F. A.—(1) About the best particulars are given in an article by Dr. König in the "B.J." of November 6, 1908, pages 848-9. This number is out of print, but you can see the volume in the Library of the Patent Office, 25, Southampton Buildings, Chancery Lane, W.C. (2) In making up M-Q developer, dissolve the metol first, then the sulphite, then the hydroquinone and bromide, and finally the carbonate. In single solution this developer will keep for a month or two; much longer if the carbonate alone is dissolved in one-half of the water and the other chemicals in the other half. (3) According to the year, there are 52 or 53 issues of the "B.J." in a volume. The volume runs according to the calendar year, the present volume ending at the end of December next. We do not supply binding cases.

C. N. E.—(1) Two rows of curtains will do, but we should prefer three, little more material will be necessary and only two extra wires. (2) We do not consider two complete sets of curtains are needed; have enough black curtains to cover the entire run of glass, and in the middle, on the same wires, enough white ones to cover half the glass. (3) This depends upon the width of your material, about a yard is convenient. Allow about half as much again as the length of the glass to allow for fullness. (4) You could not very well carry out Robinson's idea with festoons. The arrangement we suggest would give equally good results; in fact, greater control can be obtained. (5) Good black casement cloth, or Bolton sheeting for the dark blinds, and nainsook or mandapolam for the white ones. (6) Any upholsterer will make the blinds for you. Most photographers find someone who can sew. A builder would fit the wires.

J. A.—There seems to be some confusion in the particulars. You say you give half-a-second exposure at *f*/16, and in the next line you say the shutter is set at 1-15th of a second. We think it is unlikely that the vibration of the shutter is the cause of the fuzziness, but it is possible that it is if the camera or the tripod is ricketty in any part. Also it may be that the plate does not come into the same position as the focussing screen. You should test this by first focussing on the focussing screen in the usual way with the largest aperture in the lens, and then, without moving anything else whatever, throw back the focussing screen and focus again on a piece of ground glass placed in one of the dark-slides, pulling out, of course, both of the shutters for this purpose. If the image in the latter case is out of focus, it is a sign that there is something the matter with the dark-slides. If you persistently find the difficulty in all the pictures you make, we think your best plan would be to send a batch of negatives and prints to the makers of the camera for their remarks.

W. A.—(1) You cannot very well get both of the things you want, namely, silence and moderately short exposures, with the same shutter. We think the Packard is a very suitable shutter for indoor use, and is almost silent. For outdoor use there is nothing better than a good roller-blind shutter on the lens hood, which will give exposures from about 1-5th of a second up to 1-50th, and can be made to give longer automatic exposures by means of one of the time-exposure valves. (2) We do not think it is possible to make a good job of retouching the uncovered corners of the negative. Your best plan would be to block out the sky part of the negative, so that it prints white, and then, if necessary, print in a tint by sunning down for a second or so; or you could make a new negative by copying a positive transparency or a good clear print from the negative after blocking out. (3) Magnesium ribbon is too slow in burning for providing the light for photographing groups of any size. You would almost certainly spoil each exposure owing to movement of one figure or another.

E. L. W.—As regards the irregular toning of the prints in the hypo-alum bath, your letter does not say anything about the one thing which very likely is the cause, and that is the mode of heating the toning bath. If the bath is heated over a flame, such as a gas-burner or other naked source of heat, we think that the irregular degrees of temperature in the toning solution are sufficient to account for the patchy toning of the prints. We advise that you should keep the toning bath hot by placing it in a vessel of ample size containing water, which in turn is kept hot by a small gas-ring several inches below it. The outside water vessel should be of such size that you can keep the water stirred, both underneath and at the sides of the dish containing the toner, keeping some form of paddle in the outside vessel for this purpose. Also, a certain measure of care should be taken that the water in the outside vessel does not become hotter than is necessary. By means of a thermometer you should be able to ascertain with sufficient closeness how much hotter the water in the outside vessel must be in order to keep the toning bath at the required temperature. If it so happens that you have been heating the toning bath in this way, then we must look for the cause of the patchy toning in another direction. We do not think that your method of development need give you any uneasiness. For toning by the bleach and sulphide method it is certainly better to have minimum exposure and maximum development, but, on the whole —that is to say, with most papers—that does not apply to the same degree with hypo-alum toning. We think the sugar makes no material difference to the process.

Contents.

SUMMARY.

Photographic assistants whose employment brings them within the provisions of the Shops Act, have occasion to be grateful to the King's Bench Division of the High Court for a judgment (reversing that of a magistrate), which has made it plain that it it a breach of the Act for an assistant to be employed at another shop under the same proprietorship on the weekly half-holiday. We give the report of the judgment on page 672, and comment upon it on page 665.

At a recent meeting of the Council of the Professional Photographers' Association, it was decided to proceed with the formalities for the incorporation of the Association. (P. 677.)

A safety method of packing large photographs for postal transmission is described in a paragraph on page 666.

Two correspondents give their experience of means found effective for keeping studio roofs watertight. (P. 679.)

We refer to a recent notable example of the use of photographs by an educational body in its appeal to the public for funds. (P. 665.)

In the first part of a chapter on the elementary optics of the size of image produced under various circumstances, an explanation will be found of the Gauss planes and nodes of a lens and some particulars of their positions in a number of compound lenses of modern type by British makers. (P. 667.)

Colonel R. J. S. Simpson contributes a formula for the calculation of the nodal space of a lens alternative to that recently published by Mr. Lockett. (P. 679.)

The first portion of the Traill-Taylor lecture delivered by M. L. P. Clerc on aerial photography, dealt with practical considerations such as the use of light filters, design of shutters, sensitive material and build of camera. (P. 669.)

The causes of veiled or degraded negatives connected with the reflection of stray light upon the plate from the interior of the camera or from the lens surfaces are the subject of a leading article on page 666.

We greatly regret to announce the death on Tuesday last of Mr John Spiller, at the great age of 83 years. (P. 673.)

At the Royal Photographic Society, on Tuesday evening last, papers arranged by the Scientific and Technical Group dealt with sulphide toning, isocyanine colour-sensitisers and a revised wet-collodion process. (P. 676.)

A bromide printing machine worked by a self-contained electric battery is the subject of a recent patent specification. (P. 673.)

Looseness of plates in their holders is an occasional cause of unsharp definition in the use of a large aperture lens. (P. 666.)

EX CATHEDRA.

University Customers. Photographers who live in towns where there is a University or other large educational institution should take the opportunity of seeing a booklet which has just been issued by the University of Bristol. It is an appeal for funds, of which the University of the West stands greatly in need. But it is significant that in addressing itself to the public the committee intrusted with the appeal for financial help should employ almost exclusively a photographic method of showing the public what is being done. The booklet is actually a 18 page album of 172 photographs, representing every educative and social phase of the University life and reproduced in rotogravure. The fact that an important educational body should rely exclusively upon a pictorial method for making an appeal to the public for funds is a striking example which, without doubt, will be followed by other bodies. The photographer on the spot should obtain business of this kind, which requires a good deal of stage management and can be more satisfactorily carried out by a photographer in touch with local affairs. Moreover, as we have many times emphasised in similar cases, the photographer who undertakes such work should be sufficiently enterprising and familiar with photo-mechanical reproduction to undertake the contract for the entire printing job.

* * *

The Business of a Shop. The deferred judgment delivered in the King's Bench Division last week gives a legal precision to an important provision of the Shops Act which has hitherto been lacking. We quote the report of the case on another page, where it will be seen that the appeal related to the case of an assistant employed by the proprietor of two shops. On the weekly half holiday of the shop where she was regularly employed she was engaged in the other establishment of the proprietor. The magistrate, to whom this alleged breach of the Shops Act was laid by the London County Council, held that the employment in the second shop was not a breach of the Act. The judges of the King's Bench Division, however, have held otherwise, and, in reversing the magistrate's decision, have given an exposition of clause 1 of Sect. 1 of the Shops Act which is clearly in accordance both with common sense and the deliberate wording of the Act. The judges point out that the words of the Act are carefully chosen. It is provided that on one weekday in each week a shop assistant shall not be employed "about the business of a shop" after half-past one. The deliberate use of the words "a business of a shop" instead of simply "a shop" is evidence of the intention of the Act to provide for the protection of assistants employed by a proprietor having several shops; and the judgment usefully serves to give legal weight to this wider interpretation. In view of the many photographic businesses having several shops

under a single proprietorship the judgment should receive the attention of photographic assistants.

* * *

Packing Large Photographs. It is a matter of some difficulty to ensure that portraits upon large mounts, say, 14 x 11 and over, reach their destination without injury. Usually a large quantity of corrugated paper and string is used, and even then the risk of bending is considerable. A little dodge which we saw recently appeared to solve the problem. A piece of stout strawboard about two inches larger each way than the prints had four strips of wood about ¾ inch in section fastened round the edge with ordinary tin tacks, so as to make a shallow tray in which the prints wrapped in brown paper were laid, a second piece of strawboard was tacked on, and the whole wrapped in an outer cover. The wooden strips can be obtained from any timber dealer and need not be planed. If a number of one size were required they could be ordered cut to the necessary lengths, otherwise a small saw is needed. As such packages are almost invariably sent by parcel post, it is not necessary for them to be open for inspection. It would, perhaps, be an improvement to fasten the lid with glued or gummed strips as being easier for the customer to open, but most people are able to open a box in these days of postal trading.

* * *

Bellows. Sag of the camera bellows, due to the softening action of the damp atmosphere on leather, cloth or glue, is particularly liable to occur at the present time of year, but unless the bellows are very much the worse for wear may be prevented by suitable renovation. For stiffening, the bellows should be extended to the full and a coat of thin glue applied to the inside and one of good varnish to the outside. If the bellows are in a very bad condition two coats of glue may be required. Both coatings should, of course, be allowed to get thoroughly dry before the camera is returned to use. It will, however, be found that this means is insufficient to give the required stiffness to leather which has lost its substance through age, but usually it is enough in conjunction with the employment of a pair of elastic bands for hitching the bellows forward and upward to the lens front. Two elastic supports of this kind are a good deal better than the one which is commonly provided on cameras.

* * *

A Cause of Unsharp Negatives. Those photographers who use the ordinary book-form dark-slides should be on their guard against a possible source of unsharp negatives, sometimes met with, though the exact cause of the defect is not so readily apparent. We refer to the gradual weakening of the springs upon the metal division, so that there comes a time when these fail to press the plate into correct register. Recently, we were asked the reason why certain negatives taken with a well-known anastigmat lens, and focussed with the aid of a magnifier to the finest point of sharpness, were unsharp when the lens was used at full aperture, while, when smaller stops were employed, the definition upon the screen and upon the resulting negative showed no difference. Suspecting that the cause of the trouble was some defect in the lens, the photographer sent the instrument to the makers who returned it, saying that it was in perfect working condition. The fact that the negatives were sharp with the smaller stops and unsharp when the lens was used at full aperture, pointed to inaccurate register, and the trouble was eventually traced to the cause mentioned above. Another point not often realised by many workers is that the double book-form slide should never be loaded with only *one* plate, especially if the springs upon the division are inclined to be weak, as in this case the plate may not be kept in correct register. If, for any reason, only one plate is wanted in the slide, the other half should be loaded with an old negative, thus avoiding a likely cause of trouble.

HARMFUL REFLECTIONS.

When we consider the delicate gradations which should exist in good portrait negatives, and to a lesser degree in those of landscape subjects, it is difficult to imagine why so little care is taken to prevent the access to the plate of every ray of light, except that needed to reproduce the lights and shades of the original. It is true that the old axiom that a perfect negative should show a few points of clear glass no longer holds good, because this assumes that there are in every subject some portions which are absolutely non-reflective, and in practice this is rarely the case. There is, however, no reason why the smallest amount of light which is not reflected by the original should be allowed to reach the plate and degrade the scale of tones, if it can possibly be prevented.

The commonest cause of such degradation is reflections from the interior of the camera, the tube of the lens, and in some cases from the lens-surfaces. Practically all cameras are now provided with bellows bodies, and the danger of reflection from these is small, if the fabric is perfectly black and dull. But this condition cannot be long maintained without occasional attention, since the black coating has a tendency to become grey partly by a kind of bleaching process and partly by dust which adheres more or less firmly to the surface. This defect is easily removed by applying a coat of dead black colour or varnish to the fabric. A very good idea of the state of the bellows may be got by laying a piece of black velvet upon the bottom folds, opening the lens and looking through the camera back, the head being well covered with the focussing cloth. The increasing use of anastigmatic portrait lens which illuminate the interior of the camera to a much greater degree than did the old portrait lenses, emphasises the necessity for attention to this point.

Local fogging is frequently caused by reflections from the wooden framing of the camera, and this is often difficult to detect, since the eye may not be placed in a position in which the reflected light can be seen. It is a good plan to cover all edges which may be the cause of trouble with black velvet or black flock paper, thus safeguarding them against the strongest light which may fall upon them. In hand cameras which have wooden bodies, *e.g.*, the French model stereoscopic instruments, there is great danger of a bright object outside the limits of the plate causing a patch of light to appear on the side or bottom of the body, which, when reflected on to the plate, gives rise to a general or local fog. In one case of this kind a great improvement was effected by lining the whole body with velvet. The woodwork inside reflex cameras should be carefully examined and treated where necessary, the mirror support being frequently far from safe in this respect. It is, of course, necessary that the lens should face a bright light while the camera body is being inspected, or a false idea of safety may be obtained.

Lens reflections are more difficult to deal with, especially if they arise from the glass surfaces and not from the inside of the tube. In both cases they may be minimised by effectually shading the front lens by means of a hood or curtain, and in the case of lenses with long tubes a velvet or flock paper lining should be fitted.

There are some excellent matt black varnishes on the market, but the best of them fall short of the surface of velvet or other dead fabric. They may, however, be applied with advantage to the rims of the lens cells and to the edges of the rings which hold the iris in position.

An excellent aid to brilliancy will be found in the outside diaphragm recommended by Mr. Chapman Jones. This consists of an opaque non-reflecting card with an opening approximately of the proportions of the plates in use. It is adjusted at such a distance from the front of the lens as will intercept all light from reaching beyond the edges of the plate. For studio work, such a mask may be fitted to the ordinary vignetting rod of the camera, and manipulated as in vignetting. The value of this appliance when working against the light for "Rembrandt" or "edge light" effects can hardly be appreciated without trial. It is also of great value when using electric light, where it is sometimes difficult to shade the lens effectively. Almost equally efficacious, but not so convenient in application, is a similar mask or diaphragm interposed between the lens and the plate. Such a contrivance was recommended more than forty years ago by the late J. H. Dallmeyer, and it may be safely assumed that if it was necessary with the slow collodion plates of that period, it is still more so in these days of 500 H. and D.

On the principle that prevention is better than cure it is advisable to see that, when working in the studio, very light objects, such as white backgrounds and reflectors (not to mention mirrors), do not occupy positions in which their surfaces, although not included in the field of view, will cast their images upon the interior of the camera. Even a brightly-lighted floor may degrade the shadows, as may easily be proved by taking a negative with and without a dark rug upon the ground.

Those who have the good fortune to work in a well-screened north-lighted studio do not experience nearly the same amount of trouble as those who have to endure a certain amount of sunlight upon the glass, but in any case it is obvious that light that is not necessary cannot be other than injurious, the only question being one of degree. It is certain that more brilliant images would be obtained upon ultra rapid plates if every precaution were taken that no light, except that actually forming the image, reached the plate. It goes without saying that the lens should be absolutely bright and clean, or all efforts to obtain unveiled negatives will prove fruitless.

SCALE OF OPTICAL REPRODUCTION.

[The arithmetical calculations relating to the size of the image formed by a lens are among those which have frequently to be made in such diverse branches of photographic work as, for example, copying and enlarging, aerial photography, and lantern and cinematograph projection. The following article deals with this subject. The present chapter adopts the Gauss conception of the action of a lens as a simple method for derivation of the rules of optical image formation. It considers in particular the case of objects at a distance which is great relatively to the focal length of the lens, thereby emphasising the disturbing effect of depth of focus on certain scale calculations. It also presents the rule determining the relative exposures for different scales of reduction or enlargement. In Part II., to appear in a subsequent issue, the formulæ and rules contained in the present chapter are arranged in a form corresponding with the various conditions occurring in practice, with examples of their use.—Eds. "B.J."]

PART I.

The calculations relating to distance of object and extension of camera when photographing objects on various scales of reproduction with lenses of different focal length are based on a very simple optical law which follows from the construction of a lens and can be readily verified by experiment.

This law can be most easily explained by making use of the elegant method introduced by C. F. Gauss (1777—1855) for the graphic construction of the image of an object formed by a lens. We owe to Gauss the conception of the *nodes* and *nodal planes* of a lens, also called *principal* or *Gauss points* and *planes*. If the positions of these are known, and also the focal length of the lens, such problems as those involved in making calculations of the size and position of the image are made extraordinarily simple. Gauss replaced the cumbrous and complicated plan of tracing the course of rays through a lens according to the curvatures and refractive powers of its component glasses by one which requires no knowledge of these optical values. He showed that every lens possesses two nodes (usually but not necessarily within the space of the lens), and that in a well corrected lens these nodes provide the means of constructing the image from the object without knowing anything about the actual course traversed by the rays in their passage through the glasses.

The Nodes of a Lens.

In fig. 1 the disposition of the nodes N_2, N_1 in a single lens is shown. A ray of light entering the lens obliquely so that it reaches the node N_2 (called the *node of admission*) behaves as though, so to speak, it were jumped parallel with itself to N_1 (the *node of emergence*), continuing a straight course after this lateral shift. In other words, its behaviour is as though, on reaching N_2, this node instantaneously carried it straight forward to N_1, whence it proceeds parallel to its original path.

If we imagine planes P_2 P_2 and P_1 P_1, passing respectively through the nodes N_2 and N_1 perpendicularly to the axis of the lens, we shall come upon the property of the nodes which

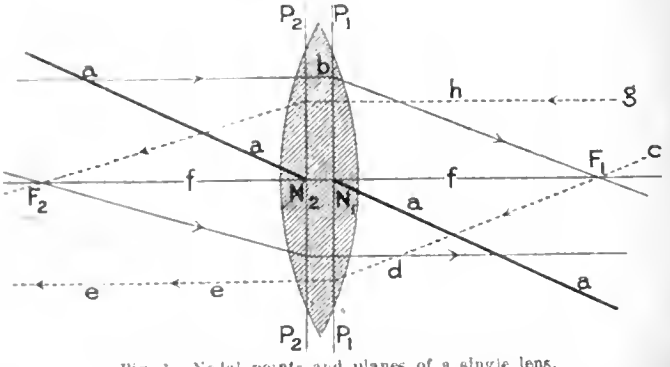

Fig. 1.—Nodal points and planes of a single lens.
P_2 P_2 and P_1 P_1 are the nodal or principal planes having the nodes N_2 and N_1 respectively on the lens axis.

is of chief importance in tracing the formation of the image. It is that a ray of light *ab* parallel to the axis, on reaching the lens, behaves as though it passed undeviated to the *plane of emergence* P, and was there bent so that it passes through

the focus F_1 of the lens. The distance on the lens axis from the plane of emergence, that is from the node of emergonce, to the focus F_1 is the focal length of the lens, which we will call *f*.

Inversely, a ray of light *cd* which reaches the lens after having passed through the focus F_1 behaves as though it continued its course undeviated to the plane P_1, and thence, undeviated, parallel to the lens axis, as at *ee*.

If rays of light are allowed to fall upon the lens from the opposite side (as would actually be done by turning the lens back to front), what was previously the node of emergence becomes that of admission, and *vice versâ*. In fig. 1, a ray *gh* parallel to the axis behaves as though it proceeded undeviated to *its* plane of emergence P_2, and thence in a straight line to the focus F_2 of the lens. Again, the distance on the lens axis from F_2 to N_2 is the focal length *f* of the lens; and in like manner a ray of light which has passed through F_2 behaves as though it continued undeviated to its plane of admission P_2 and thence parallel with the axis.

It will be seen from this very simple imagery that we may look upon every lens as having a rear focus, say F_1, and a front focus F_2, respectively situated from the nodes N_1 and N_2 at a distance *f* (the focal length) on the lens axis.

The Nodes in Practice.

Although imaginary features, the nodes occupy in every lens fixed positions relatively to the lens mount and to each other. In a single symmetrical bi-convex lens their positions are as shown in fig. I, that is, about one-third the maximum thickness of the lens from each surface. In symmetrical doublet lenses both are usually close together and near to the diaphragm. In the case of many lenses, however, particularly those of modern construction, the nodes are irregularly placed. A lens, therefore, requires to be placed nearer to or further from the plate according as its node of emergence lies towards the front or the back. In the telephoto lens, to choose an extreme example, both nodes are a considerable distance in front of the lens, so that a length of camera extension equal to the distance from the node of emergence to, say, the lens flange is dispensed with. In most lenses, however, the nodes occur in or near the lens mount, and their positions can be noted as such-and-such a distance in front of or behind the diaphragm.

In the rules and formulæ which follow relating to scale of reproduction, the distance of the object from the lens is presumed to be that from the admission node of the lens; the distance from lens to image (*i.e.*, to the sensitive surface) is that from the node of emergence of the lens. (For convenience in writing, this latter distance is referred to as "camera extension.") Only by this means can the rules connecting object and image distances, focal length of lens and scale of reproduction be made precise. Depending on the construction of a compound lens, it may be sufficiently accurate to regard both nodes as situated very close to the diaphragm.

There is no reason why any user of a lens should not find the position of its nodes. If the focal length *f* of the lens is known and a distant object be focussed on the ground glass, the node of admission is obviously at the distance *f* from the image of the sharply focussed distant object. By directing the front of the lens towards the screen and again focussing a distant object, the position of the second node is found in like manner.

A prettier method of finding the positions of the nodes is based on the fact that if the lens is supported on a vertical axis which passes through the node of emergence the sharp image of a distant object remains stationary on the focussing screen when the lens is turned through an angle. This method can be carried out by supporting the lens on any convenient holder (such as that shown in fig. 2), mounted on a rotating table. The table is rotated on a pin *A* (driven into a supporting base), which passes through one or other of a series of holes drilled in the table perpendicularly below the lens axis. If the holder is accurately made of the V pattern shown in the drawing, the holes will be directly below the axis of any lens which the V's will support; that is, if they are made in the line connecting the points of the two V's. A distant object is focussed on a piece of ground glass placed squarely behind the lens. The table is then turned on its pin, which,

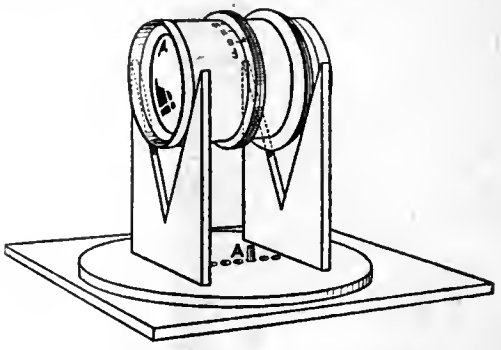

Fig. 2.—Rotating lens holder for measurement of position of nodes.

almost always, will have the effect of moving the image on the screen. By pivoting the table successively through other holes, and also by shifting the lens backwards or forwards a little on the V's, a point of rotation is found at which the image remains stationary when the table is turned. The node of emergence of the lens is then perpendicular over the axis *A*. The position of the other node is found by repeating the test after turning the lens back to front in its holder.

Positions of the Nodes in Some Lenses.

The following table gives the distances of the nodes from the diaphragm in a few of the lenses by British opticians. It will be seen that in most cases the nodes are near to the diaphragm; in some lenses both on one side; in others, one on each side. The distance between the nodes is the *nodal space* entered in the last column.

Lenses are occasionally met with in which the nodes are "crossed," that is, the entrance node is nearer to the image than is the exit node. The nodal space is then a minus distance. The Dallon (telephoto) lens and the Wray portrait lens in the table are examples.

We can now turn to see how the properties of the nodes provide the means of constructing the image, and shall see the fundamental relation between the quantities concerned in calculations relating to scale of reproduction.

The Geometry of Image Formation.

In fig. 3 let N_1 and N_2 be the nodes of a lens. P_1P_1 and P_2P_2 the corresponding nodal planes. Let F_1 and F_2 be the rear and front foci, so that $F_1N_1 = F_2N_2 = f$ (the focal length of the lens).

Let ab be an object having its lowest point on the lens axis bb_1. The position of the point a in the image may be found by drawing two rays, one AP_1, parallel to the axis and thence

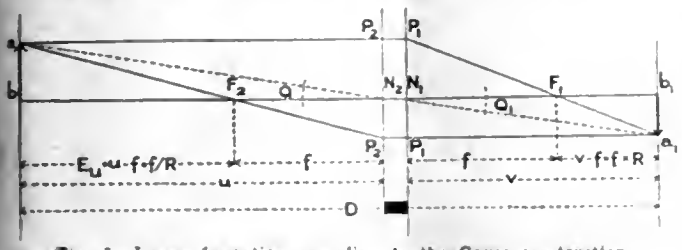

Fig. 3.—Image formation according to the Gauss construction. In the diagram f is the focal length of the lens; u, the distance of the object, or object conjugate distance; v, the distance of the image, or image conjugate distance. D is the image-to-object distance less the nodal space shown as ■.

through the rear focus F_1; the other, through the front focus F_2, to the plane of admission P_2, and thence parallel to the axis. The meeting point a_1 of these two rays is the image of a.

In like manner the position of any other point can be found. The image of b obviously lies on the axis in the same plane as a_1, viz., at b_1. Hence a_1b_1 is the image of ab.

A very little geometry will now serve to show the relation of object and image to their respective distances from the nodes N_2 and N_1. From a draw a ray to N_2 and from N_1 draw a ray to a_1. aN_2 is therefore parallel to N_1a_1, and the angles Q and Q_1 are therefore equal. The triangles abN_2 and $a_1b_1N_1$ are therefore similar, and hence

$$\frac{a_1b_1}{ab} = \frac{b_1N_1}{bN_2}$$

Calling the distance of the image v and the distance of the object u (as shown in the lower part of the diagram)

$$\frac{\text{image}}{\text{object}} = \frac{v}{u}$$

This linear ratio of image to object is usually denoted by R, *i.e.*,

$$R = \frac{v}{u} \quad . \quad . \quad . \quad . \quad . \quad . \quad (a)$$

Note that the distances u and v are interdependent. They are the so-called *conjugate focal distances*. For every value of u there is a corresponding value of v; that is to say, the scale of reproduction is not proportional to v by itself nor inversely proportional to u by itself, but is strictly equal to the ratio of these distances when an object at a given distance is in focus. We shall see, however, that in certain circumstances u may be so great compared with v (very distant objects), that v becomes practically equal to f (see fig. 3), in which case since f and u are not interdependent distances, the scale of reproduction is separately proportional to the focal lengths of different lenses used at the same distance or inversely proportional to the distances of the object when using a lens of given focal length. This relation, however, holds good, even approximately, only under certain conditions. See "Scale Calculations and Admissible Error in Size of Image" below.

For purposes of calculation it is convenient to express the value of R in terms u and f or v and f.

In fig. 3 the triangles abF_2 and $F_2N_2P_2$ are similar, whence

$$\frac{N_2P_2}{ab} = \frac{F_2N_2}{bF_2}$$

By the construction, $N_2P_2 = a_1b_1$ (the image), $F_2N_2 = f$ and $bF_2 = u-f$.

Therefore

$$\frac{\text{image}}{\text{object}} = R = \frac{f}{u-f} \quad . \quad . \quad . \quad (b)$$

Similarly from the triangles $a_1b_1F_1$ and $P_1N_1F_1$

$$\frac{\text{image}}{\text{object}} = R = \frac{v-f}{f} \quad . \quad . \quad . \quad (c)$$

Obviously these formulæ hold good rigidly on the assumption that there is no "depth of focus" when photographing objects at different distances.

These three formulæ (*a*), (*b*), and (*c*) are the fundamental relations determining reproduction to scale, and hold good in all circumstances (excluding depth) always on the assumption that the lens forms an image (free from aberration) in a flat field perpendicular to its axis. The exception relates to the formation of images of different sizes, of an object at different distances, without alteration of the camera extension owing to depth of focus. See below under "Scale, Focal Length and Depth of Focus."

The formulæ may be given other forms to fit particular conditions or for facilitating calculation.

(To be continued.)

AERIAL PHOTOGRAPHY AND PHOTO-TOPOGRAPHY.

The Twenty-fourth Traill-Taylor Memorial Lecture. Delivered by M. L. P. Clerc at the Royal Photographic Society.

SINCE I received, last year, the invitation of the Traill-Taylor Memorial Committee to deliver the twenty-fourth Traill-Taylor Memorial Lecture, I have always been convinced that such an honour was a tribute to my native land and to the photographic work of my compatriots, more qualified than I am as representatives of French photographic science, but I am very pleased to have been so chosen.

The hazards of the war took me from the trenches, where I served as a non-commissioned officer, to be appointed as a draughtsman in the first Section of Aerial Photography, established in December, 1914, where I had to second a very young officer totally unacquainted with photography in general and more specially with photo-surveying, and to devise in the field, without any means of scientific experimentation, a photographic technique adapted to this very special branch of photography. Later, I was appointed as an instructor in photography, and I was able to spend my leisure time in some theoretical and experimental work. Being not sufficiently enthusiastic in some official orders, I was dismissed and sent in a squadron to have the command of the photographic section, where I had the opportunity to verify the good application of the rules I had taught during eighteen months. I left aerial photography in March, 1918, to serve as a military chemist attached to the control of the benzine found on captured German aeroplanes.

The subject of aerial photography and photo-topography has become so large and important that it is impossible to do justice to it in a single lecture; the most that I can hope to do this evening is to describe briefly some apparatus, and some principles used in this comparatively new branch of photography, avoiding all duplication with so valuable papers as those already published by Messrs. Chas. W. Gamble, C. M. Williamson, P. R. Burchall, M. N. McLeod, and others, of which a list will be appended to the text of this lecture.

Apparatus and Materials.

Lenses.—While the British and American opticians have succeeded in producing special lenses of fine quality, with a larger

relative aperture than French ones, insufficiently supplied in optical glass of requisite qualification, it seems that no sufficient attention has been paid to the variation of the focal length and of the location of nodal points when the temperature is lowered, as it is at a height of 15,000 to 20,000 feet, frequently attained in war-time, and a very convenient one for precise topographic work. A Berthiot's Olor lens of 21 inches focus, cooled from about 75 deg. to zero Fahrenheit, has its focal length increased by one-half per cent. Such a variation, which frequently is aggravated by a contraction of the body of the camera, is detrimental to the sharpness of the image and introduces an appreciable error in the use of aerial photographs in surveying. A French patent granted to the "Société d'Optique et de Mécanique de Précision" provides against this variation by a compensation between the thermic effects on the glasses by the thermic effects on the mount, made of concentric tubes of brass and of "invar" metal. Minor variations of the focal length are a consequence of varying the aperture of a lens containing some residues of spherical aberration, but an easy remedy is the use of a fixed diaphragm. It would be very desirable that some marks be engraved, as in Cooke lenses, on all parts of the mount, to show the correct screwing and avoid variations of the focal length and of the quality of the image by insufficient or by excessive screwing. I will add that some lenses have been disabled by an interversion of their respective parts due to the fact that the number of the lens was engraved on one part only of the mount.

Light-Filters.—The optical equipment of an aerial camera is not complete without a set of light-filters, the importance of which was fully realised in the German army since the beginning of the war; a number of German cameras were fitted, inside or outside, with movable filters easily controlled by the operator, who had only to turn a lever for placing, changing, or removing them.

The extreme importance of light-filters in aerial photography is a consequence of atmospheric haze that the late Sir W. Abney has shown to scatter blue rays and transmit in preference yellow light. For aerial photography all the ground appears as the distance in an ordinary open landscape, and a satisfactory photograph cannot be obtained without the precautions customarily taken in tele-photography, viz., use of chromatic plates and of very absorbent light-filters. I spent more than three years without fully convincing the staff of the French Air Force of the absolute necessity of the technique. We were never supplied with panchromatic plates, but about in equal quantities with ordinary and with green-sensitive ones, the chromatic sensitiveness of which was not sufficient to permit the regular use of light filters of a greater absorption than a K.1 filter. For using ordinary plates it would have been necessary to possess æsculine filters; I made urgent requests during three years before receiving such a filter, and I received it only after it was known that they were in use on some German apparatus. Fortunately, the British Photographic Air Service, and afterwards the American one, adopted the only logical

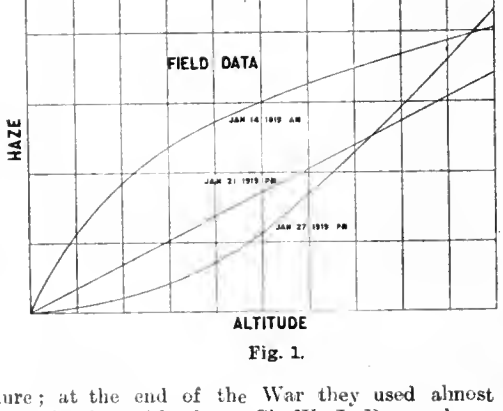

Fig. 1.

procedure; at the end of the War they used almost exclusively panchromatic plates (thanks to Sir W. J. Pope, whose work is too well known to need recalling), and intense light-filters, very short exposures being permissible due to the wide aperture lenses and to the high chromatic sensitiveness of the plates.

I owe to the courtesy of Dr. C. E. K. Mees the loan of some slides showing the researches on quantitative and qualitative effects of atmospheric haze undertaken by the workers of the Eastman Research Laboratory in co-operation with the U.S. Bureau of Aircraft Production. "In the determination of haze, test objects were utilised consisting of three squares of canvas 50 ft. square, one as white as it could be painted, another grey and the other black. The camera used permitted four photographs to be taken simultaneously through different coloured filters; it was one having three lenses, the fourth one being replaced by blocks of flat glass corresponding in absorption to the other lenses. Through the fourth comparison area a scale of densities was impressed on the plate, under a sensitometric tablet. The instrument was employed by flying over the field in ascending spirals and photographing, at intervals of 500 or 1,000 ft., the test objects on the field, sets of pictures through the different filters thus being obtained from which measurement of the apparent brightness of the areas could be determined and the amount of haze present at different altitudes could be deduced. The haze was expressed mathematically as the relation of the exposure effect produced by the black area at any altitude compared with that produced by the black area near the

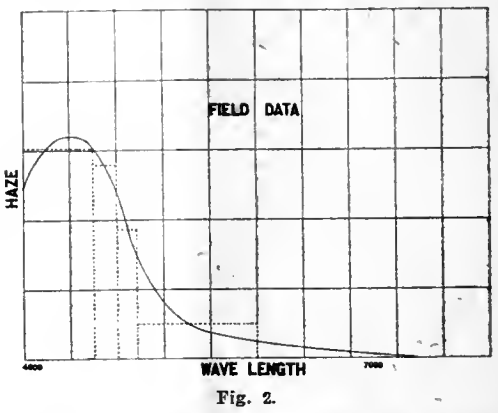

Fig. 2.

ground when the haze was negligible, this being expressed as a proportion of the total intensity deduced from the brightness of the white area measured at the same time. The results obtained showed that the distribution of haze in the air usually follows one of three types (represented by fig. 1). The haze was found to be much less as the wave-length of the light increased; fig. 2 shows the haze wave-length curve as finally calculated. A mathematical calculation was made of the amount of haze due to the molecules of air *alone*, which was found to be about one-fifth of that found in practice.

"The quantitative results thus obtained as to the distribution and colour of haze were used to duplicate in the laboratory the atmospheric conditions; in front of a camera lens was an attachment by means of which a veiling haze could be superimposed upon the image of the test object; this veiling haze was produced by a lamp which was screened by colour filters to the colour which was found experimentally to represent the average colour of haze in the air. The light from this lamp was diffused by an opal glass and reflected from a semi-platinised reflector, transmitting also the image of the test objects, consisting of squares similar to those used in the field. Between the lamp and the reflector was interposed a large neutral wedge, by means of which the intensity of the haze could be modified. From the plates exposed in this haze cabinet a reading of contrast was obtained, and curves were then plotted of this contrast factor against the amount of veiling; the exposure (fig. 3) and development (fig. 4) were found to influence the contrast obtained very greatly, and only through a narrow range of exposures could the best results be reached." It was found that an orange filter, such as the Wratten E filter, enables a panchromatic plate to photograph through a strong haze between the clouds, but not through the clouds themselves (these specimens have been reproduced in Ives' "Airplane Photography," without any reference to their source, as many other documents used in this book).

It would be necessary, in the calculation of lenses to be used in photo-surveying of a high precision, to consider the light-filter as an integral part of the lens, in order to avoid the various aberrations resulting from the use of the most perfect light-filter. For commercial and for reconnaissance work, such a precaution is neither necessary nor advisable, as photographs must sometimes be taken by poor light, and it is convenient to be able to change the light-filters and in some cases to use, in place of a contrast filter, a special filter for the detection of camouflage. Wide aper-

ture lenses are obviously of great advantage, enabling the use of intensely coloured filters.

Shutters.—With only one exception (namely the Lamperti automatic camera, used by the Italian Army, and also on some scouting planes of the French Army), all cameras used by all armies engaged in the War were equipped with focal-plane shutters without always using these to their last advantage, too great a distance being frequently allowed between the plane of the blind and the sensitive plate.

If substantially built, the focal-plane shutter is very convenient for reconnaissance or pictorial aerial photography, and also for

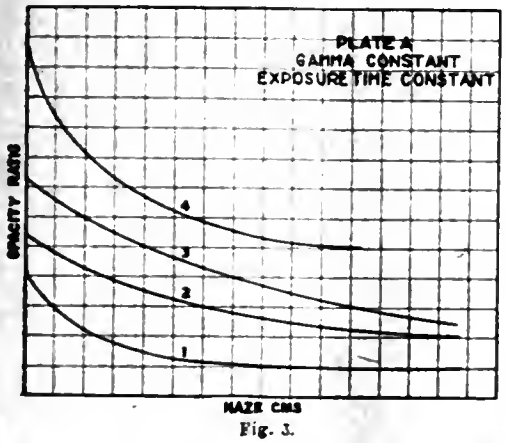

Fig. 3.

mapping on a very reduced scale; but the focal-plane shutter must be rejected for precise cartographic work. Without reproducing here the calculations that can be found in my book, "Applications de la Photographie Aérienne," let me state that the displacements of a high-speed aeroplane, and at times its oscillations by rolling or pitching, during the time used by the slit of the shutter to run over the width of the image (not much less than the tenth of a second for the whole plate size), is the cause of deformations of the image (elongation, compression, or torsion), the error of location of a point on the ground being in some cases more than 15 ft., when photographed vertically.

A palliative has been used by O. E. Messter in some of the last models of the roll film camera (*Reihenbilder Kamera*), with which Germans obtained photographic mosaics of some quarters of London and of Paris; the blind is moved alternately, for consecutive photographs, forward and backward; alternate elongations and compressions can sufficiently compensate themselves for approximate work.

One defect frequently encountered with some makes of focal-plane shutters is the slow initial movement of the blind, the speed of which grows progressively; the image shows then a strip of 1 inch or so in width, considerably over-exposed, requiring local reduction of the negative, unless some vignetting device be fitted in the camera to project a penumbra on this part of the plate. The building of a central shutter with high efficiency and sufficient speed to be used on rapid aeroplanes at a height of about 6,000 feet, sometimes required for photo-topography on big scales, such as cadastral work, is a very difficult problem. To give an exposure of three to four-thousandths of a second, at an efficiency of about 60 per cent., with a lens the aperture of which has a diameter of 3 inches, it is necessary to give to the leaves of the shutter a speed of about 140 feet per second; practically, such a speed cannot be given to a mechanical piece starting from stillness.

Two equivalent solutions have been recently given to this problem by French inventors: MM. Poivilliers and Dumont have devised a shutter of the five-sectors type, and M. Guilleniet a shutter of the double circular guillotine type. In each of these shutters the sectors, or the perforated discs, are constantly moved at uniform speed, and supplementary sectors or discs permit of selecting only one of the periodic openings at the will of the operator, or at regular intervals controlled by some automatic mechanism; in the first named of these shutters the motor is an air-turbine, concentrically mounted, which acts as a gyroscopic stabiliser. Of course, such shutters are large and heavy mechanisms, but there is no serious objection to this unavoidable state of things.

Size and Shape of the Image.—Opinions are very divided on the question of the most advantageous shape, and some people have been astonished at the general choice of an oblong shape instead of a square one; their principal argument is that a square is the quadrilateral of the greatest area which can be inscribed in the circle bounding the field of the lens. Let me note that on either side of a maximum the variation is low, and that the loss of field due to the use of usual shapes is almost negligible; almost all the armies had adopted, at the end of the war, the French size, 18 by 24 centimetres (about 7 by 9½ inches), on which the useful field is 17 by 23 centimetres; the square incribed in the same circle has a side of 20¼ centimetres (20.22); the loss of area when adopting the square instead of the oblong is of about 4 per cent. (391 square centimetres instead of 409 square centimetres). But two reasons operate in favour of the oblong shape.

While the consecutive photographs can be taken at all frequencies required for a sufficient overlap, it is not always easy to ensure the overlap of the parallel flights necessary to cover a wide field; the elongation of the shape of the image, transversely to the line of flight, is therefore of great advantage; this advantage was fully realised in the *Reihenbilder Kamera* of the German army, the images of which measured 2 inches parallel to the flight and 10 inches transversely.

Experience shows that on aerial photographs taken in fine weather from an aeroplane conducted by an able pilot, the vertical plane, which is perpendicular to the plane of the plate, makes usually a very acute angle with the plane of symmetry of the aeroplane. The calculations I have made ("Brit. J. Phot.," vol. 66, May 30, 1919, pp. 297-299) on the limit of admissible angling in vertical photography have shown that the area of the oblique photograph susceptible of being united with the vertical photograph taken from the same view-point is limited by a curve the form of which recalls that of a *Nicomedes conchoid*, of which the directrix is parallel to the horizon-line of the photograph; a plate of elongated shape tranversely to the flight is therefore more suited for photographing the best portion of the field covered by the lens.

Plates or Roll Films.—The question at present so much discussed in British photographic circles is not stated in the same terms with respect to aerial photography: the choice is limited to plates or to roll film, as the cut film would involve all the inconveniences of both plates and films.

The advantages of the plate are chiefly its rigidity, the fact that the image, solidly bound to the rigid support, is practically undeformable, the possibility of developing without any intricate appliance, and the possibility of quick drying for emergency work. We must, however, point out that F. E. Ross ("Astrophysical J.," vol. 52, September, 1920, pp. 98-109) has discovered some deforma-

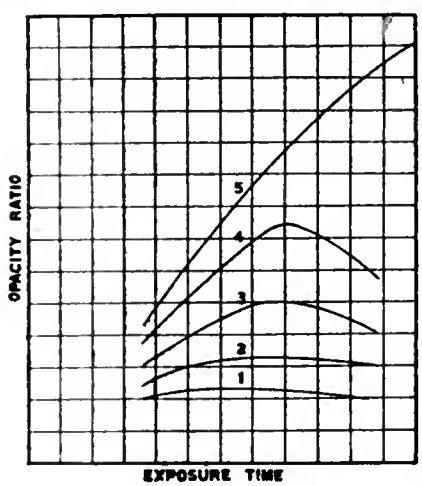

Fig. 4.

tions on the image by contraction of the gelatine due to the use of tanning developers or to uneven drying.

The advantages of the roll film are its lightness and the simplicity of the feeding, but it is known that a film does not keep its dimensions, but suffers a shrinkage during the photographic manipulations, this shrinking being not always uniform, and varying with the age of the film and with atmospheric conditions.

To permit subsequent use in mapping on a mean scale of photographs made on roll films for mosaic work or for preliminary maps at a very low scale, it would be necessary to register in the camera,

on the four sides of each image, either some metric division or squaring, or some marks, the distance of which is an aliquot fraction of the focal length, or, more precisely, of the principal distance, actual distance of the exit nodal point from the plane of the sensitive film.

Some device must be provided to ensure the flatness of the film in the focal plane: three typical devices have been used to do so. In the Libmann camera the film is applied to a patent-plate glass by the pressure of a felted board, pressure being released when winding the exposed part of the film; the same device has also been described in one of H. Workman's patents. In the German film camera the support glass was sometimes used as a yellow filter. In the Eastman K.1 automatic film camera, and also in a R. Aubry's apparatus, and in a film-changing box patented by Zeiss, the film is drawn against a flat plate by means of suction applied through numerous small holes in the plate; this suction is furnished by a Venturi tube mounted on the outside of the fuselage of the plane. In Boucher-Duchatellier's Aerophote the film is stretched by slipping between the velvet edged blind of the focal-plane shutter and a bridge located behind the slit; the edges of the slit touching the film during the travel of the blind, the efficiency of the shutter attains 100 per cent.

As is well known in cinematography, the friction of the celluloid back of the film against all surfaces with which it comes in contact produces static discharges, registered in the image as arborescences; the United States Air Service has been able to avoid these discharges by holding in contact with the celluloid, during its travel from one reel to the other, a cloth impregnated with graphite and connected with the metallic parts of the camera.

Body of the Camera.—The extended use of metals or metallic alloys for building the body of aerial cameras may be criticised in the case of apparatus equipped with long-focus lenses and designed to be used above 10,000 feet or for precise surveying; the contraction of ordinary metals, when cooled by about 75 deg. F. (a not infrequent cooling in flights at 15,000 feet) is about 1 per 1,000 of their length—that is to say, a shortening of half a millimetre for the distance of the lens to the plate in an apparatus using a lens of 50 centimetres focus; such a shortening introduces an error in the measurement of the principal distance, an essential datum for photo-topography, and spoils the sharpness of the image, giving for the image of a point a circle of diffusion the diameter of which is one-tenth of a millimetre if the aperture of the lens is one-fifth of the focal length.

The metal construction could preferably be done by using a practically non-expansible metal, such as the "invar" alloy (a special nickel-steel), the variations of which are about 4 per cent. of those of aluminium or duralumin, or by some device comparable to the compensating pendulum of some clocks. To reduce to a minimum the possibility of alterations under varying conditions of temperature and moisture, the best plan seems to be that adopted by the Royal Naval Air Service, at Mr. Chas. W. Gamble's instigation (I believe): A framework is made of four longitudinal members, constructed of well-seasoned mahogany, slit into three and reversed, glued together, the whole bar being then treated with paraffin wax; this framework is securely fixed to stout aluminium castings, one for the lens board, the other for the shutter case; the sides of the framework are then plated with duralumin sheets, not fixed, but free to move in grooves running the length of the members.

Some German cameras captured in the last year of the war were equipped with electrical heating coils, connected with the general heating and lighting current supplied by an electric generator driven by an air propeller; such a heater, or the heating envelope patented by the French Government, avoids the troublesome effects of cooling on the sensitiveness of the photographic emulsion, on the operating of springs and of rubber-covered blinds, on the viscosity of lubricating oils; it avoids also the condensation of moisture on the photographic plates when the aeroplane descends, but not the condensation on the external surface of the lens.

L. P. Clerc.

(To be continued.)

A Link with the Past.—Former photographer to the English and French Royal Families, Charles Taylor has died at Sidcup at the age of 79. He had a studio at Chislehurst during the Empress Eugenie's residence there, and his patrons included Queen Victoria. Mr. Taylor, we are told, took the last portraits of Napoleon III. and the Prince Imperial at Camden House, Chislehurst.

THE BUSINESS OF A SHOP.

An Important Judgment on Assistants' Half-Holidays.

In the King's Bench Division on Thursday last, November 3, the Lord Chief Justice, Mr. Justice Sankey, and Mr. Justice Acton gave judgment in favour of the London County Council in a case which raised the question whether employees in multiple shops could be transferred to a shop belonging to the same proprietors other than that at which they normally worked on the day fixed for their weekly half-holiday under the Shops Act, 1912.

As reported in the "Times," a confectioner named Wettman was the occupier of two confectioners' shops, one at 263, Old Street, London, E.C., and the other at 30, Goodge Street, W.C. On December 8, 1920, between 5.30 and 6 p.m., an inspector employed by the appellants found that a female shop assistant who usually worked at 30, Goodge Street was employed dressing the window at 263, Old Street. December 8 was a Wednesday, and Wednesday was the day of the week fixed by the respondent pursuant to the Shops Act, 1912, for the weekly half-holiday of his employees.

The respondent was brought before the Old Street Police Court for failing to comply with Section 1, Sub-Section 1, of the Shops Act (which provides that on at least one week day in each week "a shop assistant shall not be employed about the business of a shop" after 1.30 p.m.), but the magistrate dismissed the information.

The following facts were proved or admitted at the hearing of the information: (*a*) The respondent was the occupier of two confectioner's shops in London, one at 263, Old Street, E.C., and the other at 30, Goodge Street, W.C.; (*b*) the shop assistant, Miss Wilson, to whom the proceedings referred, was employed by the respondent in his shop at 30, Goodge Street; (*c*) Wednesday was the day of the week fixed by the respondent for the weekly half-holiday of Miss Wilson, pursuant to the Shops Act, 1912; (*d*) on Wednesday, December 8, 1920, an inspector visited 30, Goodge Street, and seeing the respondent there asked where Miss Wilson was. He replied that she was having a holiday. The inspector then went to 263, Old Street, the respondent's other shop, where he found Miss Wilson employed about the business of that shop, dressing the window, between the hours of 5.30 and 6 p.m.

The Lord Chief Justice read the judgment of the Court, in which he said: We assume from the findings in this case that the assistant was employed at Old Street with the knowledge and consent of her employer. It is, therefore, unnecessary to consider the case of Ward v. Smith (29 *The Times* L.R., 536; [1913] 3 K.B., 154). On the point of law raised by this case the magistrate held that he was bound by the words of Mr. Justice Channell in George v. James (30 *The Times* L.R., 230; [1914] 1 K.B., 278)—namely, "The words 'a shop assistant shall not be employed about the business of a shop' mean 'about the business of the particular shop in which he is an assistant.'" He then appears to have assumed that, on the facts found by him in this case, a shop assistant employed in dressing the window of the shop at 263, Old Street was not employed about the business of the shop at 30, Goodge Street. It is here that we do not quite follow him. In our opinion it is open to the Court to accept the words of Mr. Justice Channell as they stand in relation to the facts of the present case (very different, by the way, from those in George v. James) and yet to decide, with all respect to the magistrate, that the conclusion that he arrived at was wrong.

The words "employed about the business of a shop" clearly are, and are intended to be, capable of very wide application. They may readily be contrasted, for example, with such words as "employed in a shop" or "in or about a shop," which are the words found in Section 2 (1) of the Act. With regard to the words "the business of a shop," strictly speaking, a shop cannot be said to be a business. "The business of a shop" or "a shop's business" is, indeed, to the logical mind a figurative expression. It may, we think, be fairly paraphrased for the purposes of this case as the business carried on in the shop by the shopkeeper. Here the business carried on by the respondent at the shop in Goodge Street was that of the retail sale of confectionery. But he did not carry on that business at Goodge Street exclusively. He also carried on that business at 263, Old Street. He carried on that business partly in one shop and partly in the other. On these facts it seems to us to be no straining of language to say that a person employed by the respondent in window dressing at 263, Old Street was employed "about the business" carried on at 30, Goodge Street or, in other

words, about the business "of" the shop at 30, Goodge Street, although, of course, not "in" nor "in or about" that shop. On the contrary, to say so appears to us to be in accordance alike with strict reasoning and common sense. In the sense which we have sought to make clear, the business "of" the shop at 263, Old Street was also the business "of" the shop at 30, Goodge Street, and for the purposes of this decision there is no valid distinction to be made between them. And certainly to hold otherwise would, in the words of Mr. Justice Channell in George v. James "be opening a wide door to evasion of the Act." We think that the magistrate was wrong in dismissing the information, and that this appeal must be allowed.

DEATH OF MR JOHN SPILLER.

THE news was announced at the Royal Photographic Society last Tuesday, November 8, of the death in the early hours of the morning of that day, of Mr. John Spiller, one of the oldest members of the Society, and its president for the years 1874-1875. Mr. Spiller was 88 years of age.

He was a scientific member of the firm of dye-makers of Brookes, Simpson & Spiller, was among the leading early experimenters in photography, and worked in collaboration with the late Sir William Crookes. Their joint labours are particularly remembered in the

Photograph by Alfred Ellis & Walery.

JOHN SPILLER F.I.C., F.C.S.

Crookes-Spiller process of preserving the sensitiveness of the semi-dried wet-collodion plate which, so to speak, bridged the gap between the wet plate of Scott Archer and the collodion dry-plate of Hill Norris. As was pointed out recently in these pages by Mr. E. J. Wall, Mr. Spiller appears to have been the first to suggest and to prepare a silver printing paper containing the gold required for its toning—a forerunner of the modern self-toning paper. A chemical paper of his which afterwards had a photographic application of importance, was one on the solvent powers of the alkaline citrates on many inorganic substances. The use of citrate in the copper toning solution of Mr. W. B. Ferguson is an instance of the later employment of these properties.

Up to four or five years ago Mr. Spiller retained an extraordinarily large measure of vitality and preserved the spring and physical energy of one thirty or forty years his junior. His striking resemblance to the late Lord Roberts was frequently the cause of his being taken for the eminent soldier by men of various military ranks. His cordial disposition made him welcome in the circles of membership of chemical and other scientific societies which he frequented until a few years ago, and his death removes one of the veterans of photography who have witnessed its development from almost its origin.

FORTHCOMING EXHIBITIONS.

November 17 to 19.—Bowes Park and District Photographic Society. Particulars from the Hon. Sec., S. Smith, 68, Mannock Road, Wood Green, London, N.22

November 23 to 26.—Rotherham Photographic Society. Particulars and entry forms from the Hon. Exhibition Secretary, Sydney G. Liversidge, "Orissa," Gerard Road, Rotherham

December 3 to 17.—Scottish Photographic Circle. Hon. Secretary, W. S. Crocket, 10, Parkgrove Terrace, Tollcross, Glasgow.

1922.

January 21 to February 4.—Partick Camera Club. Latest date for entries, January 30. Particulars from the Hon. Secretary, James Whyte, 51a, Peel Street, Partick Glasgow.

February 11 to 25.—Scottish Photographic Salon. Particulars from the Secretary, James F. Smellie, Braefindon, Allanshaw Street, Hamilton.

February 14 to 17.—Exeter Camera Club. Particulars from C. Beauchamp Hall, Hon. Exhibition Secretary, Exeter Camera Club "St. Denys," Bellevue Road, Exmouth.

Patent News.

Process patents applications and specifications—are treated in "Photo-Mechanical Notes."

Applications, October 24 to 29 :—

CAMERAS.—No. 28,455. Photographic cameras. J. W. Beaufort and J. H. Hewitt.

ENLARGING.—No. 28,705. Apparatus for producing photographic enlargements with multiple impressions. C. Costantini.

DEVELOPING APPARATUS.—No. 28,273. Apparatus for developing, etc., photographic films. W. J. Crowe.

LANTERN-SLIDES.—No. 28,294. Production of slides for optical projection apparatus. Howells Cine Equipment Co. and D. P. Howells, Ltd.

COMPLETE SPECIFICATIONS ACCEPTED.

These specifications are obtainable, price 1/- each, post free, from the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C.

The date in brackets is that of application in this country; or abroad, in the case of patents granted under the International Convention.

BROMIDE PRINTING BOXES.—No. 169,359 (October 23, 1920). The box *a* is of wood and fashioned to contain electric batteries marked *b*, lamps *c c'* and switch *d*.

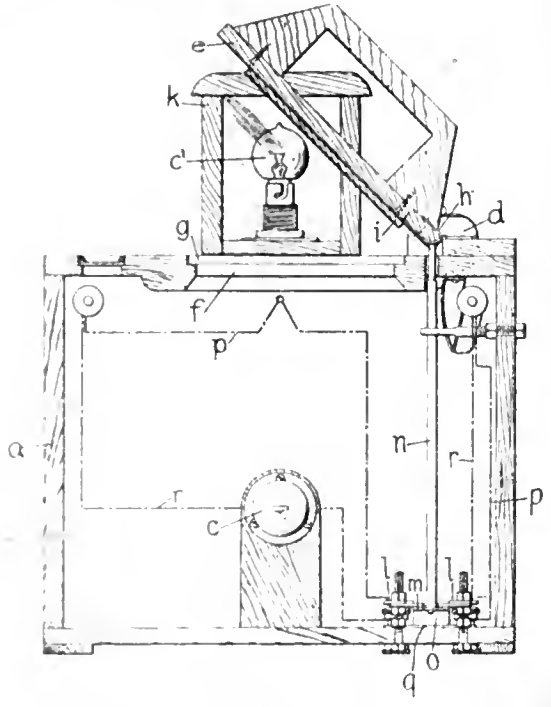

Fig. 1.

On the inner side of the lid *e* of the box means are provided for receiving the plate and the card to be printed.

The top of the box *a* is formed with a suitably sized opening *f* in the centre thereof, recessed or countersunk around its upper edge to form a ledge *g* (see fig. 1); the lid *e* hinged at *h*, being formed with a corresponding raised portion *i* on its under sur-

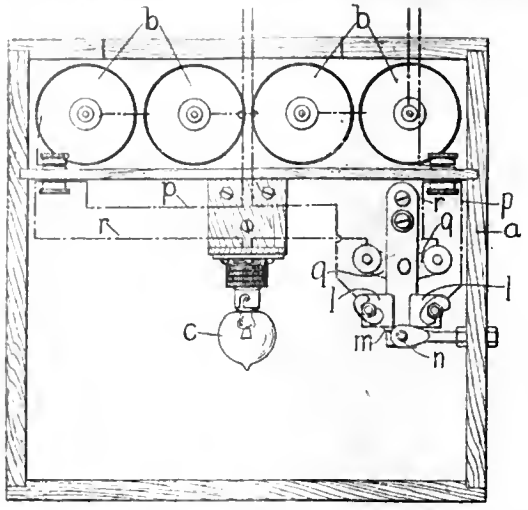

Fig. 2.

face to fit in the opening—a cavity and frame thus being formed to contain the plate, and the card to be printed is inserted in the same.

A red lamp c^1 is housed in a casing *k* mounted upon the box *a*, and by opening the lid *e*, the lamp is lighted when the current is on, the current being controlled by the switch *d*.

l, *l* are terminals mounted within the box *a*, and *m* is a contact carried upon the vertically arranged rod *n*, which serves to close the circuit by the action of a spring *o*.

The upper end of the vertical rod *n* makes contact with the rounded rear edge of the lid *e* in such manner that as the lid closes the rod is depressed, and overcoming the action of the spring *o*, breaks the circuit *p* of the red lamp and bridges the

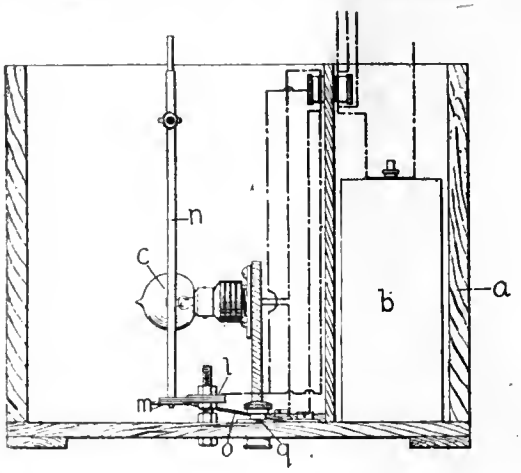

Fig. 3.

contacts *q* and closes the circuit *r* of the lamp *c*, but as the lid is opened the upper end of the rod is released from pressure and the spring *o* operates to raise the rod bridging the contacts *l*, and close the circuit *p* of the red lamp c^1.

After placing the card in position, the lid *e* is closed, which operation breaks the red lamp contact and closes the circuit of the white lamp, the latter lighting up when the lid is closed tightly.

The card is exposed for 3 to 5 seconds with three or four dry cells.—Herbert Booker, Woodside Road, Chiddingfold, Surrey.

The following complete specifications are open to public inspection before acceptance:—

PHOTOGRAPHY.—No. 170,595. Photography. M. de Sperati.

CINEMATOGRAPHY.—No. 170,560. Method of and apparatus for producing tone films. W. Greaff and P. Dresla.

CINEMATOGRAPH-PHONOGRAPH.—No. 170,561. Apparatus for taking animated pictures and recording tone oscillations. W. Graaff and P. Dresla.

Trade Names and Marks.

APPLICATIONS FOR REGISTRATION.

TYRCO.—No. 416,784. Cinema screens of linen, not in the piece. Eben Williamson Morrison, 940, Sauchiehall Street, Glasgow, merchant. July 8, 1921.

MARKS PLACED ON THE REGISTER.

The following marks have been placed on the register:—

TREFOIL DESIGN ("AS DE TREFLE").—No. 416,088. Photographic paper. Grieshaber Frères & Cie., also trading as Société des Produits Photographiques "As de Tréfle," 27, Rue du Quatre-Septembre, Paris, France, manufacturers.

NOVABROM.—No. 416,635. Photographic printing paper and postcards. Photo-Produits Gevaert (Société Anonyme), 23, Sapta Straat, Vieux-Dieux, Belgium, manufacturers of photographic materials.

New Materials.

Mounts, Calendars, Passe-Partouts, and Albums. Made by Houghtons, Ltd., 88-89, High Holborn, London, W.C.1.

QUITE a variety of new introductions in the shape of mounts, etc., for the forthcoming season reach us from Messrs. Houghtons. Among them are a series of very attractive Christmas mounts of the folder slip-in pattern, with appropriate designs and mottoes in colour on the fronts. These mounts are sold in sets of six, for prints from V.P.K. to postcard, at prices from 1s. 3d. to 1s. 6d. per set.

The calendar mounts are in two styles, one the ordinary mount, with slip-in space for a print from V.P.K. to postcard, sold at prices from 4d. to 7d. each, for oblong prints only. The base of the mount is a stout board surfaced with a paper of grey velour

Fig. 1.

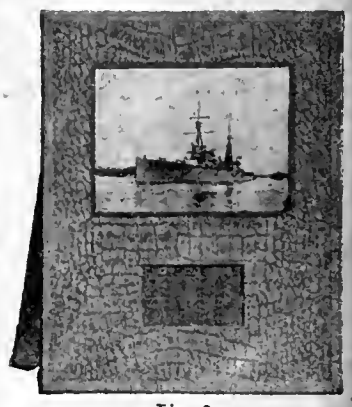

Fig. 2.

texture, providing a very pleasing imitation of crocodile leather. The tear-off calendar appears below the print. The illustration (fig. 1) by no means represents the very artistic appearance of the mounts.

In calendar passe-partouts Messrs. Houghtons have some exceedingly pleasing designs. Fig. 2 shows a ready-made passe-partout, made in the oblong and upright patterns. The print has simply to be slipped into position at the top of the mount. Again, the surface is the grey velour already mentioned, which is mounted outside the glass, the latter protecting the print slipped behind it. These complete passe-partouts, in sizes from V.P.K. to postcard, are priced from 1s. 3d. to 2s. each.

Another novelty in passe-partout mounts is shown in figs. 3 and 4. It is a self-contained passe-partout fitted with a strut back of special cut, which allows of the mount being supported either in the

upright or oblong position. In the grey velour finish these passe partout frames are supplied in sizes from V.P.K. to postcard, at prices from 9d. to 1s. 3d. each.

Fig. 3.

Fig. 4.

Lastly, in albums Messrs. Houghtons offer a number of new styles, among which we particularly like the "Carlton" (fig 5), a slip-in album, with padded rounded covers of most artistic appearance. The

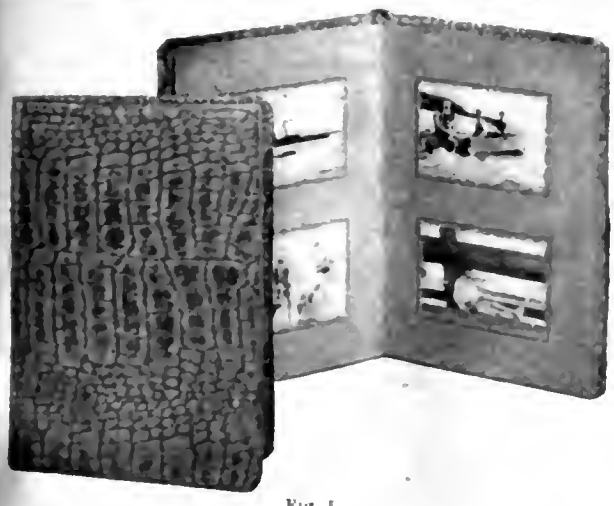

Fig. 5.

leaves are appropriate in colour to the covers, and give a double-line border to each slip in opening. Each album accommodates 24 prints, two on a page. In sizes from V.P.K. to postcard, the prices are from 3s. 3d. to 4s. 9d.

Ensign Passe-Partout Outfits.—The artistic mounting of photographs in the passe-partout style is being further popularised by the issue by Messrs. Houghtons of a series of complete outfits, including mounts, back boards, glasses, binding strip, adhesive and hangers. The outfit is put up in three sizes: No. 1, for prints up

to 5½ x 3½ inches, price 7s. 6d.; No. 2, for those up to 6½ x 4½ inches, price 9s. 6d.; and a third for prints up to 8½ x 6½ inches, price 13s. 6d. The illustration shows the attractive form in which the requisites are boxed. Outfits of this kind, providing indoor occupation, should contribute to maintain the interest of amateurs in photography during the winter months.

Venus Retouching Pencils.—Messrs. Alpco Pencils, Ltd., 173-175, Lower Clapton Road, London, E.5, send us specimens of the most recent addition to their series of retouching pencils. In addition to the series of Venus pencils in 14 degrees of hardness, from 3H to 9H, which they have hitherto supplied with great satisfaction to users, they have just issued a new pencil, No. 3818, of round instead of hexagon section. Many retouchers appear to prefer a round to a hexagon pencil, and in deference to the expressed wishes of their customers the Alpco Company have now put on the market this new pattern, which at present is made only in the soft degree. We should mention also that the price of Venus pencils has been reduced to 6d. each, 5s. 3d. per dozen, or 54s. per gross net, and that the makers have recently introduced some neat pocket wallets, price 6s., containing Venus hexagon pencils for the convenience of those users who must continually carry pencils of three or four degrees of hardness with them. The price list of the firm gives the most complete description of the many grades of lead pencils for ordinary as well as for retouching use, and also of retouching leads and refills now supplied at 2s. each and 2s. per box of six, respectively. Dealers in photographic requisites should also be interested in noting the extremely attractive style in which the Venus goods are packeted.

New Apparatus.

Ensign Amateur Dry-Mounting Outfit.—Messrs. Houghtons have just put on the market a set of outfits for the dry-mounting of prints by a modified method which is easily within the purse of the amateur worker of moderate means, inasmuch as the mounting press is dispensed with and the prints attached by means of a strip of adhesive tissue round the edges in conjunction with the use of a small hand piece for heating the tissue when in position. Each outfit contains a selection of both mounting boards and border tints, the process thus allowing of an appropriate narrow border being given to each print. The outfits are issued in three sizes for prints up to half-plate, whole-plate and 10 x 8 at the respective prices of 3s., 4s. and 5s.

Exeter Camera Club.—This club is organising an exhibition to be held from February 4 to 17, 1922, at Exeter, and to include three open classes: A, for prints of any description in any medium; B, lantern-slides in colour by any process; and C, monochrome lantern-slides. A gold medal will also be awarded for the best picture in the exhibition. Dr. C. Benuchamp Hall, St. Denys, Bellevue Road, Exmouth, is the hon. secretary, and the exhibition will be judged by Mr. Bertram C. Wickison.

Cinema Films in Schools.—There is no indication that it would be possible to make any reduction in teaching staff as the result of using the cinematograph in schools, says a report by sub-committee of the London Education Committee, who have been considering the subject. "Financially, therefore," proceeds the report, "the present is not a suitable time to embark upon any programme of cinematograph developments in schools, but rather to examine cautiously its possibilities for a more appropriate period. Meanwhile, an effort should be made to secure the elimination of undesirable features in cinematography."

Lunar Photographs.—A report of the moon section of the British Astronomical Association deals with the many additions that have been made to the map of the moon by recent photographs taken with the great 100-inch reflector at Mount Wilson, California, and suggests that a complete photographic atlas of the moon made by the same instrument would be a magnificent achievement. For example, one of the Mount Wilson photographs depicts the whole of the Mare Imbrium. A rough count of the craters and craterlets shown in this region gives a total of more than 700, of which about 300 are not found on any existing maps. It would, we are told, take an observer, using a powerful telescope, several years to detect and map all of these minute details, which have been recorded by the camera in less than two seconds!

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

MONDAY, NOVEMBER 14.

Bradford P.S. Members' Print Night.
City of London and Cripplegate P.S. "Some Points on Picture Making." B. C. Wickison.
Dewsbury P.S. "Developing Negatives." Albert Lyles.
Kidderminster and Dist. P.S. "Amateur Photographer" Prize Slides.
Leeds Camera Club. "Transferotype." W. H. Hammond.
Southampton C.C. "Anastigmat Lenses." Aldis Bros.
South London P.S. "Pictorial Ideals." M. O. Dell.
Wallasey Amateur Phot. Soc. "Bits in the Hundred of Wirral." W. Tansley.
Walthamstow & Dist. P.S. "Development." E. Willcocks.

TUESDAY, NOVEMBER 15.

R.P.S. "Some Sea Birds." Frank R. D. Onslow.
Birmingham P.S. "The History of Photography." E. C. Middleton.
Cambridge and Dist. Phot. Club. Annual Dinner.
Exeter C.C. "'Tri-Colour' Photography, Principle and Practice, Demonstrated with Diagrams, Cameras, and Prints," etc. Frederic G. Tutton.
Hackney Phot. Soc. Short Papers by Members.
Leeds Phot. Soc. "The Magic Carpet." H. Crowther.
Morley Phot. Soc. "With Cycle and Camera in North-East Yorks." H. Guy.
South Glasgow C.C. Lantern Slide Monthly Competition.
Tyneside Phot. Soc. Print Criticism

WEDNESDAY, NOVEMBER 16.

Accrington C.C. "Seltona." J. R. Killeya.
Borough Polytechnic P.S. "Printing Processes."
Croydon C.C. "Ramble with the Paget Col. Plate." F. R. Newens.
Dennistoun Amateur Phot. Assoc. "Bromoil." John Thomson.
Halifax Scientific Society. The "Amat. Phot." 1921 Prize Slides.
Ilford P.S. Lecture by Mr. Bertram Cox.
Partick C.C. First Lantern Slide Competition.
Rochdale Amateur P.S. "Thro' the Grecian Archipelago and the Near East." Messrs. Butchers.
South Suburban P.S. "London from Many Points of View." H. Creighton Beckett.

THURSDAY, NOVEMBER 17.

Camera Club, The. "Elements of Bromoil." R. Crowther.
Hammersmith Hampshire House P.S. "The Isle of Skye." Arthur Gardner, M.A.
North Middlesex P.S. "Vitegas and Novex." C. J. Gooch.
Tunbridge Wells Amateur P.A. "The Gates of the Orient." Rev. H. O. Fenton, B.A.
Wimbledon and District C.C. "That which makes a thing what it is." E. C. Perry.

FRIDAY, NOVEMBER 18.

R.P.S. Pictorial Group Meeting. "Photography in Relation to the Graphic Arts." J. Dudley Johnston.
Edinburgh Photographic Society. Social Evening.
Wombwell and Dist. P.S. Exhibition Prints.

ROYAL PHOTOGRAPHIC SOCIETY.

Meeting held Tuesday, November 8, Mr. F. F. Renwick, F.I.C., in the chair.

Papers arranged by the Scientific and Technical Group were read.

Mr S. O. Rawling, B.Sc., of the British Photographic Research Association, read a paper on sepia toning with colloidal sulphur. Experiments had been made for the purpose of examining the ability of sulphur in the colloid state to tone a silver image to a sepia colour. Sulphur was dissolved in absolute alcohol, and the solution mixed with a large quantity of water. The diluted solution was found to tone, but very slowly, requiring three hours at a temperature of about 125 deg. F. It appeared that the action did not take place in the manner ascribed to colloid sulphur by Lumière and Seyewetz, viz., by intermediate formation of hydrogen sulphide. Mr. Rawling had found that a saturated solution of the latter in air-freed water did exert a certain toning action in the heat, but very slightly. The action was retarded by reducing agents such as formaline and sulphites, and was accelerated by oxidising agents. Altogether the experiments showed that colloid sulphur was perfectly effective in toning.

The next paper, by Mr. W. T. Wilkinson on "Scott Archer's and Hardwick's Wet-Collodion Formulæ Revised," described an improved form of the process based on the use of a mixture of bromide and chloride of silver instead of iodide. An advisable proportion of bromide to chloride in the collodion was 4 : 1. The sensitising bath could then be a 60-gr. solution of silver nitrate rendered slightly acid with nitric acid. Owing to the insolubility of silver bromide or chloride in the silver solution, the difficulties of keeping the bath saturated (as when silver iodide was the sensitive salt) were not experienced. Also the sensitiveness of the plate was about twice that of one prepared with iodide.

Mr. Wilkinson explained that the exposed plate could be washed and developed with any alkaline developer. Also it could be treated with an organifier and could then be exposed dry and also colour-sensitised with the Sensitol dyes.

Mr. A. C. Banfield showed a dish of his design for the development by time of panchromatic plates. He had made it on account of the pinholes and other markings occasionally encountered in developing in a tank with vertical grooves. The dish had a loose flat bottom provided with two pairs of parallel grooves, into each of which six 45 x 60 mm. plates could be slipped end to end. An upright piece served as a handle for placing the loose plate-holder in the dish and removing it. The device thus allowed him to wipe the surfaces of the plates with his finger, and he declared that he could feel an air-bell on a plate and remove it—a statement that aroused a lively discussion and called forth completely contradictory experiences in the avoidance of air-bells when developing plates in a tank.

Mr. Renwick read, in abstract, a paper on "The Optical and Photographic Properties of some Isomeric Isocyanines," by Miss F. M. Hamer, B.Sc., of Cambridge, who had carried out experiments for Sir William Pope. Starting from the isocyanine iodide parent substance, Miss Hamer had prepared derivatives by substitution of other radicles in different places in the group, and testing the absorptive and colour-sensitising properties of the resulting compounds. The radicles substituted were the cinamaroyl-amino, acetyl-amino and amino groups, and the experiments had brought to light several excellent colour-sensitisers, and also examples of departure from the customary relation between the absorption and sensitising properties.

Votes of thanks were accorded to the authors of the papers.

CROYDON CAMERA CLUB.

Mr. H. W. G. Bidgood, representing Necol Industrial Collodions, Ltd., of 62, London Wall, E.C.2, demonstrated the various uses of its products, and is to be congratulated on a successful first appearance in the rôle of lecturer. The demonstration was a "trade" one, pure and simple, with no pretence to the contrary; it was, however, made quite interesting by Mr. Bidgood, who evidently has a thorough grasp of his subject, a feature which, if shared by all representatives of commercial houses, would render trade demonstrations more sought after by the larger clubs.

He started with a description of the various collodions made by his firm, and their many applications, incidentally revealing an intimate knowledge of several trades, particularly those in leather. In fact, he rather over-dosed his audience with leather, and will know better next time. Of course, collodion is prepared for photographic emulsions, but is only supplied in bulk, and attention need only be drawn to a few products apparently of real utility to the average man.

"Necol" household cement, just on the market, is a special collodion in collapsible tubes, and, it is claimed, will unite everything except india-rubber. When set, it is impervious to heat, is waterproof, and will even resist boiling water. China, xylonite, glass, and leather, among other things, can be dealt with. Excellent also for sticking "invisible" patches on old boots, ever grateful and comforting. A leaflet printed in red ink for those who prefer this colour to legibility, gives full particulars.

A "Necol" colourless lacquer (shortly to be placed on the market) makes an impervious negative varnish, applied cold; will waterproof anything; renovates leather, and affords a durable cold lacquer for metal. Mixed with finely ground black pigment, it gives a tenacious dead-black on metal. Specimens of a dead-

matt white surface on metal, and transparent coloured lacquers were also shown. The demonstrator next passed round a perfectly watertight developing dish composed of a thin strawboard of ultra-rotten quality. The corners had been reinforced by thin card or paper stuck with the cement, and the interior given three coats of the lacquer.

"Plastic wood" (only supplied direct) is another Necol product which appears to have many uses apart from its primary object—the making of engineers' patterns. It is a dough which can be moulded to any shape, and when set may be regarded as waterproof wood, taking kindly to all wood-working tools. Unlike the more adventurous putty, it is ideal for filling in cracks, as once in it invariably stops at home. So tightly indeed does it stick, that if any gets on the hands nothing will remove it completely except a special solution supplied for the purpose. The plastic wood can be had in half-pound tins, and it is to be hoped the special solution in quantity less than the gallons airily referred to by the lecturer from time to time, otherwise the small user may find himself in rather an awkward position.

A hearty vote of thanks was accorded Mr. Bidgood, who undoubtedly made good.

PROFESSIONAL PHOTOGRAPHERS' ASSOCIATION.

A meeting of the Council was held at 4, Southampton Row, on Friday, October 14. Present: Messrs. Adams, Basil, Bennett, Frank Brown, Chaplin, Chapman, Chase, Chidley, Corbett, Dickinson, Ellis, Gray, Haines, Hana, Illingworth, Lambert, Read, St. George, Speaight, Spink, Wakefield, Swan Watson, Wedlake, and Lang Sims (secretary).

The Secretary read a letter from Mrs. Fry and from Mr. Arthur Fry expressing their gratitude to the Council for their floral tribute and their words of sympathy. He also read the letter which he sent to Mrs. Fry on learning of the death of her husband. The Council stood in silence in memory of their late colleague, and, on the motion of Mr. Swan Watson (President), seconded by Mr. Frank Brown (ex-President), it was agreed that the secretary's letter should be entered on the minutes.

The Council, which was deeply moved, formally recorded the vote of condolence which had already been sent in anticipation by the secretary.

Mr. George Hana, with his consent, was unanimously appointed a trustee in place of the late Mr. Fry.

Mr. Reginald Vaughan (Solicitor) attended to report progress with regard to incorporation, and there was a general discussion on many important points.

Mr. Vaughan said that although this would not be an association which was known as an association "not for profit," it would be a company limited by guarantee. The company either had to have a share capital, and the liability of the members was limited to the shares for which they subscribed, or it was limited by guarantee, the amount of the liability of each member being specified. In this case the liability, in the event of winding up, was limited to ten shillings. The expression "not for profit," it was his duty to tell them, had a technical meaning. It was the heading of the section of the Act which described an association similar to the one he had mentioned, the Royal Geographical Society, where the members took no benefit. Directly the phrase was used every judge and lawyer would say that this was the kind of association. He was afraid, therefore, that it must be put beyond question, and a general meeting would be a simple way of dealing with it. The Solicitor added that the delay which had occurred had been unavoidable. He had prepared the draft of the memorandum and articles at once, but had had to wait for the Board of Trade.

The Chairman suggested that they should accept the solicitor's advice and call a special general meeting at the earliest possible moment, asking for instructions to register under the title of a limited company, limited by guarantee. He further suggested that Mr. Vaughan should be asked to draft the notice convening the meeting and to explain briefly the situation.

This was unanimously agreed to.

Before the solicitor withdrew, the Chairman, amid applause, heartily congratulated him upon the good work he had been doing on behalf of the Association.

The Secretary reported upon the case of Bone *v.* Etches, which concluded on October 11 with a verdict for Miss Bone (a member of the P.P.A.), with £150 damages and costs. The case was conducted by Mr. Reginald Vaughan, solicitor to the P.P.A. Miss Bone, of Peterborough and Hunstanton, brought an action against Mr. J. B. Etches, who formerly carried on business at Peterborough under the style of the Rapid Photo Co., which the plaintiff purchased from him in 1916. By the deed of assignment Mr. Etches covenanted not to sell photographs to any persons at less than the prices current for the time being of the Rapid Photo Co., or of the plaintiff. On the defendant's return to business after being demobilised he restarted in 1919 in the photographic trade at the old address, Narrow Street, Peterborough, under the style of the Aerial Photo Co., and issued a price list, in which he offered to do view work of "second quality finish" at prices which were less than those current at the Rapid Photo Co. and those of the plaintiff in the action.

The Secretary read a letter from the Eagle and Star British Dominions Insurance Company, Ltd., stating that they must be informed, both by new proposers and existing policy holders, if celluloid films were being used, this to be followed by inspection of premises when necessary.

The Secretary reported 24 new members (Nos. 1,602-25), 11 of which were obtained through Messrs. Houghtons, Ltd. Five resignations were also reported.

Owing to the business on the agenda, a large proportion of the business was not reached, it was therefore resolved to adjourn the meeting to Thursday, October 27.

The Council adjourned at 7 p.m. for refreshment, after which Mr. Haines described his visit to America and to the Convention at Buffalo. A vote of thanks was passed to him unanimously for his very interesting address. The President handed to Mr. Herbert Lambert a silver cup from the Vancouver Exhibition, and Mr. Lambert returned thanks to the president for his congratulatory remarks.

The adjourned meeting of the Council took place at 35, Russell Square, on Thursday, October 27. Present: Messrs. Adams, Basil, Chaplin, Chase, Ellis, Haines, Hana, Illingworth, St. George, Speaight, Spink, Turner, and Lang Sims (secretary).

Mr. Alfred Ellis took the chair.

Apologies for non-attendance were read from Messrs. Frank Brown, Chapman, Corbett, Swan Watson (president), and Wakefield.

The Secretary read a number of letters from correspondents, and his replies thereto, which latter were endorsed by the Council. A country member asked for information with regard to apprenticeships. He was referred to the particulars given in the Handbook. It was agreed that a printed form of indenture might be sent to inquirers.

A seaside member wrote stating that he had all photographic rights on the pier, and that these had been infringed by a photograph taken on the pier which had appeared in the Press. The opinion was expressed that the rights which the pier company had given could only have applied to the taking of professional photographs—*i.e.*, sittings—on the pier, and could not be interpreted in such a way as would prevent visitors from using cameras.

A country member wrote asking whether the Association had a scale of fees for photographs illustrating trade advertisements. The Secretary, in his reply, had referred him to the instructions as to copyright which appeared in the Handbook. Some discussion took place as to whether definite figures could not be quoted in such a case, and it was pointed out that no figures could have a general application, and that the matter was one for individual arrangement.

Some correspondence was read concerning a dispute between an Irish member and a firm of dealers in second-hand apparatus, regarding a camera which, in the member's view, was wrongfully detained. Through the intervention of the Secretary, the misunderstanding was cleared up so satisfactorily that the member, as some practical recognition of the work done by the Association on his behalf, had forwarded 20s. to the funds.

A country member wrote with regard to a controversy over a Press reproduction of a photograph which had topical interest, and the Secretary reported that he had had an interview with the agency concerned, and had successfully proved the member's claim to a fee.

A London member wrote concerning the carriage of his photo-

graphic apparatus by rail, stating that his operator, going on a professional engagement, had been charged 10s. for passenger's luggage. The Secretary stated that he had interviewed the Assistant Manager of the Great Western Railway, and it was pointed out to him that any luggage over and above certain small hand luggage was liable to be charged. Several members of the Council gave their experiences, which varied considerably, and the subject was adjourned until the next meeting.

Mr. Adams proposed the establishment of a permanent Propaganda Committee for the purpose of ascertaining the best method of bringing forward the claims of the Association. Such a committee might consider a co-operative scheme of advertising.

A small provisional committee was appointed, consisting of Messrs. Adams, Basil, and Speaight, to explore the situation, and furnish to the next meeting of the Council a preliminary report on propaganda, with which was bound up the question of co-operative advertising.

CAMBRIDGE AND DISTRICT PHOTOGRAPHIC CLUB.—At the meeting held on November 2, Major F. Debenham gave a lecture on "Antarctic Exploration, with Notes on Polar Photography." The lecturer, who was a member of Capt. Scott's expedition, first described the various ice formations met with, and showed lantern slides of each kind. He then dealt with the animal life found in those regions, and mentioned that the only living creatures which remained in the Antarctic all their lives were two tiny insects, which often remained frozen inside lumps of ice for several years, and on waking only had perhaps an hour's hectic life before being frozen in again. The lecturer showed some very comical pictures of penguins, and told some amusing tales in connection with them. Amongst other things, he described the dogs and ponies used by the explorers, and gave some idea of the life led by the expedition. Dealing with photographic questions Major Debenham said that among the chief difficulties met with was the condensation of any moisture on the lens and plates, and its subsequent conversion into ice crystals, which were very hard to remove. The intense cold soon upset the working of focal-plane shutters, and it was difficult to get a good rendering of rocks and snow on the same plate owing to the extreme brilliance of the snow. On the other hand, the actinic value of the light was very high; when using a Watkins meter in sunshine the paper usually took only a second to darken to the standard tint, as compared with 4 or 5 secs. in England in summer time. The absence of any haze in the atmosphere made it easy to get clear views of distant objects. The lecturer's own slides were of a high quality, and he also showed some by Mr. H. G. Ponting, and one which represented one of Capt. Scott's first efforts at photography.

MESSRS. VENTIHETA, LTD., makers of ventilating gas stoves for studio heating, to whom we recently referred a correspondent, inform us that they have removed from Argyle Street, Oxford Circus, to 311 and 324, Old Street, London, E.C.2.

Drawn by Paul Reilly. From *Judge*.

UNCROWDED PROFESSIONS: THE PHOTOGRAPHY OF CHILDREN.

News and Notes.

BRITISH SHOWROOMS ABROAD.—Premises have been secured at 9, Rue de Ligne, Brussels, for the first of the sample showrooms which are to be organised in all parts of the world by the Federation of British Industries to enable British manufacturers to display their goods to foreign buyers.

BOWES PARK PHOTOGRAPHIC SOCIETY.—The thirteenth annual exhibition will be held at Unity Hall, Newnham Road, White Hart Lane, Wood Green, N.22, on the 17th, 18th and 19th of the present month. The exhibition will be judged by Mr. F. C. Tilney, and on the opening night Mr. W. L. F. Wastell will deliver his lecture, "A Loon in London." On the two following evenings lectures will be delivered by Messrs. H. Creighton Beckett and C. P. Crowther.

A NEW CRITERION PROFESSIONAL PAPER.—Messrs. Criterion, Ltd., inform us that they are just issuing a new matt bromide paper for professional use. Its special feature is a distinctive matt surface closely resembling the natural surface of the paper. The new paper is made in three grades of contrast, ordinary, hard and extra hard. Samples will be sent to bona-fide professional photographers, and orders can only be accepted for execution in rotation.

Correspondence.

ARTIGUE'S TWO-NEGATIVE METHOD FOR SOFT FOCUS PORTRAITS.

To the Editors.

Gentlemen,—Mr. Coles' letter on Artigue's two-negative process raises a point which occurred to me and led me to experiment considerably.

Contrary to my expectations I found film almost useless for the purpose. Used in combination with a plate, it is a remarkable fact that the film, even without the addition of a thickness of glass or film, produces the effect of dreadful halation in the rear plate, as compared with the general softened effect when a plate is used, thus rendering them almost useless for this purpose. The only cause I can think of is the coating of gelatine on the back of the film causes far more scatter than its transparency would suggest.

It would be interesting to have the experiences of other experimenters.

Dreadful thought—is the glass plate of the future to rise triumphant with emulsion on both sides, and put to shame its celluloid cousin?—Yours truly, WM. ASPDEN.

234, High Street, Bangor,
November 4.

EFFICIENCY OF THE FOCAL-PLANE SHUTTER.

To the Editors.

Gentlemen,—Referring to the reply to "C. C." *re* efficiency of focal-plane shutters in your issue of October 28, I have a half-plate Thornton-Pickard focal-plane shutter fitted to a camera by one of the leading makers. The plate is ¾ in. from the blind, which, with ¼ in. slide register, leaves ½ in. for thickness of shutter frame. It would seem, therefore, that this distance precludes anything near the maximum efficiency being attained, and it may account for the fact that, with exposures short enough to stop such motion as children playing games, I get hopelessly under-exposed plates at *f*/5 5 on a sunny summer day. It appears quite unnecessary to have the shutter frame ½ in. thick between slide and blind, as there is ample thickness of frame between blind and

camera to give sufficient strength, but apparently the Thornton-Pickard Co. think otherwise.

It would be interesting to hear from readers who are experts in this work as to the actual measurements of the apparatus they use.

You suggest a blind at only ¼ in. from the plate, but I do not see how this could be obtained save with a metal slide and a shutter reduced to the minimum thickness.—Yours faithfully,

M. R. Douglas.

9, Dundonald Road,
Kensal Rise, London, N.W.10,
November 2.

LENSES FOR PORTRAITURE: COMMERCIAL v. ARTISTIC PHOTOGRAPHY.

To the Editors.

Gentlemen,—I have read with more than usual interest the correspondence on the above heading, and am particularly impressed by the statement of Mr. Basevi in your issue of October 21. It bears out the assertion of Messrs. Beck and Andrews in their first issue of "Photographic Lenses," which I am perfectly convinced holds good now as well as it did then, viz., that there has never been produced a lens for portraiture to equal the extra-rapid rectilinear. With nearly forty years of experience I have yet to meet a lens that will give a portrait to equal the longer focus Ross *f*/5.6 "Universal Symmetrical." Other equally rapid R.R.'s may be equally satisfactory in the hands of their users. Of that I have not had the experience, but I have tried the newer anastigmats by several makers, and certainly never obtained the same pleasing results as with the Ross *f*/5.6 of 12 to 20 inches focal length, and still use the 20-in. for cabinet work.

As regards those things called "art" (bless the mark) I leave that sort of thing to the few who are unable to produce pleasing detail, and are content to smother their ignorance under the cloak of what they term art.

That class of work will soon die a natural death, and would be long since buried but for the effort of certain photographic papers which have been labouring in vain to make the ordinary mortals believe they: "Have eyes and see not."—Yours faithfully,

John Francis English.

Orion Studios, Londonderry, November 1.

CHROMIUM INTENSIFICATION.

To the Editors.

Gentlemen,—In your leading article on intensification you refer to chromium intensification, and I recently carried out certain experiments to ascertain the maximum amount of intensification which is readily possible. A panchromatic plate was developed in total darkness for about half the usual time, and was given three successive doses of the chromium intensifier with a minimum amount of hydrochloric acid, and as the density was not then sufficient, a fourth bleaching was performed with the usual ferricyanide mixture used in sulphide toning, except that a little mercury bromide dissolved in alcohol was added (mercury bromide was used only because the mercuric chloride was not available), and the image was sulphided. This gave a considerable degree of extra intensification, so that the negative gave a first-rate print.

There is one point on which some information would be useful when attempting maximum intensification, i.e., with a minimum amount of acid blackening is sometimes very slow, and is much accelerated by pouring the solution repeatedly on to the negative or print, the part on which the solution falls bleaching much more rapidly than other parts. The writer is at a loss to give an explanation of this.

In using this method for prints the process sometimes breaks down on papers of the brown-black or gaslight variety, and though my experiments are not conclusive, it would appear to be safer to conduct the operations by artificial light, and when, with this precaution, double tones are still obtained, as is sometimes the case, ammonium bichromate or potassium ammonium chromate should be used in preference to potass. bichromate. The writer does not attempt to offer any explanation, as he is not a chemist, but tried the salts named as they were more easily washed out of the paper, and the results were certainly better. Some brands of B.B. paper seem to be immune from this trouble, while of others, some of the surfaces are difficult to intensify, while the remainder give no trouble; generally speaking, the more glossy the paper the greater the chance of an inferior result.—I am, Sir,

Yours faithfully,

A. H. Hall.

1, Eliot Vale, Blackheath,
November 4.

THE NODAL SPACE OF A LENS.

To the Editors.

Gentlemen,—Mr. Lockett has an interesting method of finding this in his article in the "B.J." of October 21, 1921, but his formula is needlessly complicated.

Let m and n be two ratios of enlargement, of which m is the larger; let D_2 and D_1 be the corresponding distances between the object and the image; S = the internodal space, and f the anterior conjugate corresponding to the smaller enlargement.

Then $f=(D_2-D_1)\times\frac{m.n.(n+1)}{n(m+1)^2-m(n+1)^2}$ . . . . . (1)

and $F=\frac{f}{n+1}$, $f_1=\frac{f}{n}$.

How $D_1 = f + f_1 + S$. Hence $S = D_1 - (f + f_1)$.

Further, take $m = 2n$ and (1)² becomes

$f=(D_2-D_1)\times\frac{2n(n+1)}{2n^2-1}$ . . . . . (2)

and $S=D_1-(D_2-D_1)\times\frac{2n(+1)^2}{2n^2-1}$ . . . . . (3)

Further, in the particular case where $n=2$ $m=4$, then $f=\frac{12}{7}(D_2-D_1)$

$f_1=\frac{6}{7}(D_2-D_1)$ $S=(D_2-D_1)\frac{18}{7}$ and $F=\frac{4}{7}(D_2-D_1)$

Yours faithfully,

R. J. S. Simpson.

WATER-TIGHT STUDIO ROOFS.

To the Editors.

Gentlemen,—I think the following material will interest both your correspondent "M.W.," also Mr. V. L. Wyrall, and all who suffer from a leaky roof, no matter whether the roof is glass or any other kind. This is Masticon, sold by the Industrial Engineering Co., Ltd., Poland House, 167, Oxford Street, London, W.1, who, no doubt, would be pleased to send anyone a leaflet on its use.

I have stopped a very leaky roof (glass), which is almost flat, and, owing to the water not running off quickly, used to leak with the slightest drop of rain. But since using Masticon it is quite water-tight, even with some glass which was not puttied in at all, just laid on and a coat of Masticon put on top in place of the putty. I have also stopped a matchboard building from leaking through the joints. Anyone who tries this I think will find their troubles at an end.—Yours faithfully,

Ernest Dyche.

Palace Studios, Birmingham,
November 4.

To the Editors.

Gentlemen,—The exceptionally hot summer which we have experienced has played havoc with the old-fashioned sash-lights, causing the wood and putty to part company.

The rain this week-end has no doubt caused the studio proprietors to put their "thinking caps" on in order to effect a cure "ere the winter's storms begin." Like many other things it is often the case of "Out of sight out of mind," and no matter how sound the work is, in the first instance, the upkeep must be attended to.

May I be allowed to give the benefit of my experience in connection with a picture gallery? This had three sky-lights, good, bad, and ——, according to shade afforded by the surrounding buildings, which proved that it was the action of the sun which affected them.

"Lazy people take the most pains," and our theorist got to work inside with plumbob and line to locate the point of inlet.

After sundry patchings and "dodgings up" the matter seemed even worse, so we decided to make a job of it. The whole was

thoroughly washed with weak soda water, and a sharp coat of white lead and turpentine with a very little dryers was applied, followed next day by another of stone colour. Here I must emphasise the importance of the white lead being the main foundation of the paint, and in colouring the less pigment there is the better.

If a ready mixed paint is used white lead and boiled oil should be added, but it is far preferable to mix one's own.

This did not effect a complete cure, but it became an annual institution, and *when* we at last got them water-tight we still carried on with the good work, and have not been troubled since.

While on the subject, should any of your readers have a leak in corrugated iron or zinc, I can recommend the following:—Two parts of powdered resin, one part of tallow, and a little white lead. Melt in an old baking tin, and cutting some strips of calico, dab the same in the mixture and apply hot. This will stick instanter, and can then be painted, taking care to cover the edges well. G. S.

TESTING THE VIGOUR OF DEVELOPMENT PAPERS.

To the Editors.

Gentlemen,—In my article last week I made use of the word "steep" in connection with soft papers (paragraph 10). As this word is commonly associated with the idea of vigour or contrast, my wording of the paragraph was rather unfortunate. My endeavour was to contradict the idea that soft papers (having long exposure ranges) have some inherent power of rendering a bigger number of gradations than other papers, irrespective of other factors. My meaning would have been clearer had I said: "Taking all emulsions as capable of rendering the 100 gradations which are visible to the human eye, a soft emulsion will render them from 100 steep gradations of a harsh negative, while a contrasty emulsion renders them from 100 shallow gradations of a soft negative, providing that the negatives contain 100 gradations, and are properly suited to the papers, this latter being a serious point when we have so many grades of soft, and so many of vigorous, in both negatives and papers."

THERMIT.

Answers to Correspondents.

In accordance with our present practice a relatively small space is allotted in each issue to replies to correspondents.

We will answer by post if stamped and addressed envelope is enclosed for reply: 5-cent International Coupon, from readers abroad.

Queries to be answered in the Friday's "Journal" must reach us not later than Tuesday (posted Monday), and should be addressed to the Editors.

T. F.—Bolton sheeting is to be obtained of most furnishing drapers. Messrs. B. Burnet and Co., Ltd., 22, Garrick Street, London, W.C.2, usually have it in stock. It is used for casement curtains.

M. A.—We published a specification of a drying-machine by Bates in the "B.J." of September 30 last, page 585. In 1919 we published two specifications by Morse, one in the issue of February 28, page 103, and the other December 19, page 744.

W. A.—You can obtain vanadium chloride from chemical firms such as Hopkins and Williams, 16, Cross Street, Hatton Garden, London, E.C.1, or British Drug Houses, Ltd., 16-30, Graham Street, City Road, London, N.1. The current list of the latter prices the 50 per cent. solution at 5s. per oz. In both copper and uranium toning the silver image is converted by the ferricyanide into ferrocyanide. In the copper process this latter is converted simultaneously into copper ferrocyanide, and in the uranium process into the corresponding uranium salt. We do not know what is the chemical basis of the red toning of a sulphide-toned print in a gold bath.

P. G.—The best method of storing sensitive photographic materials, both plates and papers, is in an air-tight metal box, which itself can be kept in a cool place. Very suitable boxes are the tin trunks sold by the ordinary department stores. A number of somewhat similar boxes are now obtainable at moderate prices in the shape of surplus goods; one firm is R. Black, 51, High Holborn, W.C.1. Without any further protection papers will keep for months in these conditions if the storage place is cool, and a further available means towards keeping is to provide the box with a false grid bottom and to place below this a few pounds of dry calcium chloride, which may be put in muslin bags for convenience.. When the chloride becomes damp it is only necessary to roast it thoroughly in an old iron saucepan over a fire to restore it to its original condition.

MODELS IN ADVERTISEMENT PHOTOGRAPHS.—My young lady, while in the employ of a small commercial photographer as a printer, was told to sit for two photographs, and was told they were for a catalogue No payment or agreement was made. They have now appeared on the screen of the local theatres as advertisements for the firm whose furniture was photographed. Can she in any way make the firm or the photographer take them off the screen or catalogue, or alter the photograph so as to make her unrecognisable? She has since left the employ of the photographer.—W. E. A.

We do not think that your fiancée can take any measures to prevent the exhibition of the photographs which have been taken of her in any form whatever, so long as their exhibition does not constitute a libel of her. The law defines libel as something which holds up a person to ridicule or contempt. We do not think either of the photographs which you send would be regarded as libellous.

B. G.—We should have liked to have seen the negative in order to have been able to say whether the colour is the general stain which is sometimes produced by the uranium intensifier, or the natural brownish-red image which is produced. If it is the former, hypo will account for it, although generally the stains in this case are patchy. We should try soaking the negative for a quarter of an hour or so in a weak solution of ammonium sulphocyanide which, as a rule, will remove general stain produced by the uranium intensifier. For thoroughly washing a few negatives there is no better method than laying them, film up, on an inclined board down which a stream of water constantly passes from a short length of tube arranged transversely at the head of the board and perforated every quarter-inch or so by a fine hole. This uses little water and is very efficient. We think half an hour's washing in this way is ample. It should also be sufficient for ordinary purposes to give the negative a succession of 7 or 8 five-minute soaks in successive lots of clean water, but if intensification with mercury or uranium is to be done a longer washing is necessary, as either method is, so to speak, a delicate test for hypo in the film.

The British Journal of Photography.

The Oldest Photographic Journal in the World.

PUBLISHED EVERY FRIDAY. **ESTABLISHED 1854.** **PRICE FOURPENCE.**

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 3211. Vol. LXVIII. FRIDAY, NOVEMBER 18, 1921. Price Fourpence.

Contents.

SUMMARY.

The publishers' supply of the 1922 "B.J. Almanac" is practically exhausted. Intending individual purchasers are advised to place their orders immediately with a photographic dealer, bookseller or bookstall. (P. 681.)

Mr. R. R. Rawkins in a contributed article, describes how to make a folding mask for convenient production of white-margin enlargements. (P. 684.)

In a leading article we refer to some of the points raised in a recent controversy in these pages on the respective commercial merits of what may be termed "ordinary" and "exhibition" portraiture. A conclusion is that no matter how "ordinary" a photographer's work may be, it is to his interest to cultivate artistic aims and equally to interest the public in things artistic. (P. 682.)

In a further portion of the paper on scale in optical reproduction the condition under which the size of image is proportional to the focal length of the lens is defined from two points of view; the rule governing the variation of exposure when photographing on different scales of reproduction is also explained. (P. 685.)

Dr. B. T. J. Glover examines proposals for a contrast rating of printing papers, and comes to the conclusion that a set of comparison prints will serve the photographer more effectively than will such sensitometric rating, as could be stated by the paper makers. (P. 694.)

The concluding part of the Traill Taylor lecture, recently delivered by M. L. P. Clerc on aerial photography, reviews types of cameras, methods of suspension, and choice of photographic material. It also contains a brief survey of the methods hitherto employed in aerial mapping. (P. 688.)

Aerial photographic survey is to be employed in planning the proposed new road between London and Southend. (P. 693.)

In a paragraph on page 682 we remind assistants in studios that in the event of their posing in photographs they have no subsequent remedy whatever as regards the use which may be made of the results.

The essential provisions of the Business Names Act, particularly as they affect photographers, are set forth in a pargaraph on page 681.

Notes on the use of the uranium intensifier will be found in a paragraph on page 682.

Mr. T. P. MacNally describes and illustrates a simple device for ensuring the secure action of dark-slide clasps. (P. 695.)

A French inventor, M. Ratier, has patented a modification of the Ozobrome process. (P. 691.)

EX CATHEDRA.

The 1922 Almanac. At the request of our publishers we announce that almost the whole edition (of 30,000 copies) of the 1922 "British Journal Almanac" has been disposed of to the distributing firms in the photographic and bookselling trades. It must, therefore, be pointed out to individual would-be purchasers of the book, who have not yet placed an order with their photographic dealer, bookseller, or bookstall, that their means of now ensuring the delivery of a copy is to place an order without delay in one or other of these quarters. Our publishers desire it to be known that within the next few days they will be unable to supply further copies either singly or for re-sale. The price of the "Almanac" remains the same as that of last year, namely, 2s. net in paper covers; 3s. net in cloth binding. Although high costs of production continue to prevail in the book-publishing trade, we believe it will be found that the "Almanac" preserves its customary usefulness to photographers of all classes. It may be said that there is no photographic process for which it does not contain particulars of both standard practice and of latest developments. These and other data, including a directory of the photographic trade, are revised and supplemented, and make the "Almanac" the most up-to-date of reference volumes for the photographic work-room or office.

* * *

The Business Names Act. Some recent correspondence shows that there are still a number of people who entertain a very hazy idea of the nature of the registration of business names. One correspondent, who wrote to us a day or two ago for information, was of the view that by registering the fancy name under which he carried on a studio he obtained the means of keeping his own name undisclosed, as he wished to do for family reasons. In fact, of course, the object of the Registration of Business Names Act is exactly the opposite. This war-time measure, passed for the purpose of preventing the resumption of businesses here by ex-enemies under British titles, makes it a civil offence to carry on a business under a name other than that of the true name of the proprietor unless the assumed business name is registered at the office established for the purpose at 39, Russell Square, London, W.C.1. Further, any business which thus comes within the scope of the Act is required to comply with certain provisions. The chief of these is that the real name of the proprietor, whatever the nationality of the latter, shall be stated upon "essential business literature." This definition is understood to include ordinary note heading, invoices and other stationery by means of which business transactions are carried out. In the case of photographic studios it is, however, not required that the real name of the proprietors should be published on the mounts of the photographs themselves, on view postcards, or in any adver-

tisements which the firm may issue; nor is it required that the real name should be displayed outside or inside the place of business. A circular, explanatory of the provisions of the Act, may be obtained on application to the address given above.

* * *

Rights in One's Face. Although under the present Copyright Act a very wide scope of ownership is conferred in respect to the right of reproduction of original works of many descriptions, there is still nothing in copyright law which enables a person to restrain anyone from publishing or using photographs of the person's face which by some means or another have been obtained. We are speaking now of portraits produced in circumstances in which the copyright does not become the property of the subject, as, for example, the snapshots of people such as are reproduced in the newspapers. The absence of means of protection under such conditions as these sometimes gives rise to somewhat curious disputes. A case was referred to us recently in which a girl assistant had posed in two photographs, advertising furniture, taken by her employers for a firm of manufacturers. The latter then used the photographs as advertisement lantern-slides in the local cinema theatre, where, apparently, the identity of the model was recognised by many friends. Assistants who are asked to pose in photographs taken in these circumstances should, however, bear in mind that they have no control whatever over the subsequent use of the photographs in any shape or form by the owners of the copyright. Such use can be restrained only if the publication or exhibition of the photographs constitutes a libel of the subject; and even if it is thought that the photographs are objectionable in this respect, it is extremely doubtful if any action could be successfully taken if the photographs in the first instance were made with the consent of the model.

* * *

The Soft-Focus Cure. Particularly in the United States the soft-focus lens is being pushed as a species of elixir which automatically imports the desirable quality of "art" into a portrait. New soft-focus objectives continue to appear on the market. While the softening of definition has its obvious merits, the tendency to apply soft focus indiscriminately to portraiture generally is one which requires to be resisted. Already it is evident that the practice is creating a technical form which tends to destroy much of the strength and variety of the camera portrait. We are inclined to think that the method of M. Artigue, described in our issue of October 21 last, is a surer means of preserving photographic quality in combination with such diffused definition as may be necessary, and we are encouraged in that belief by hearing from Mr. N. E. Luboshey that this identical method has been practised by him for the past twenty years, and was, in fact, the subject of a demonstration at the Vienna Photographic Society some years ago. Mr. Luboshey tells us that he used it in making the portraits of Mr. Eastman and Dr. Rodman shown at the last R.P.S. exhibition and cordially reviewed by the critics.

* * *

The Uranium Intensifier. The recent dull weather has perhaps been the cause of a crop of questions, which has reached our table, relating to uranium intensification. Let it be said at once that for a negative, which has been under-exposed and has taken its chance along with others in time development, or has been "forced" in dish development, there is no better intensifier than uranium. The degree to which detail, together with respectable contrast in the print, is obtainable must be a revelation to those who have not tried this intensifier. It needs, however, to be emphasised that the negative must be both thoroughly fixed and thoroughly washed, otherwise a disastrous result in the form of patchy stains is almost a certainty. One correspondent complains of a uniform yellow staining of the negative, which makes printing extremely slow. The reddish-coloured uranium negative is, of course, not a quick printer, but its defect in this respect may be aggravated by a residue of yellow stain from the uranium salt. A solution of ammonium sulphocyanide (5 or 10 grs. per oz. of water) will usually clear away this general stain. Another querist inadvertently applied the intensifier to a negative which had retouching on it, with the consequent result of absence of intensification on the parts of the negative thus protected. The remedy in this case is to clean off the retouching with turpentine or ether and remove the intensification, and at the same time clean up the surface of the film by swabbing it with cotton wool dipped in ammonia solution. After washing, the negative may be re-intensified, preferably after soaking it for a few minutes in a weak solution of acetic acid.

EXHIBITION AND COMMERCIAL PORTRAITURE

THE somewhat desultory discussion which followed the letter by Mr. Godfrey Wilson in our issue of October 7 provoked diametrically opposite views on a subject which concerns every portrait photographer, but did not result in drawing conclusions which to us appear to follow naturally from the very discordance of the opinions expressed. It may be well, therefore, to glance again at the issue in dispute.

It will be remembered that Mr. Wilson felt disappointed at the examples of portraiture—for the most part by professional photographers—in the exhibitions of the London Salon and the Royal Photographic Society; disappointed, because he found himself unable to discover there scarcely any portraits having (from the fact of their exhibition) a kind of certificate that they are "Art," and also a character which, in his opinion, would recommend them to the customers of a studio. If they were one, they were not the other. He confessed to finding only one which he believed would satisfy the second condition as well as the first, namely a portrait by Mr. Drummond Young. In regard to this expression of discontent, it is almost so obvious as not to need pointing out, that the writer was adopting as a standard of comparison something which is highly variable, viz., "really good professional studio portraiture." Photographers' own opinion of work which may be so described is wide enough; and that of the public, which is what really matters, wider still. Impossible, then, to point to this or that example of portraiture in the exhibitions as a type to be emulated.

But when the apostles of artistic expression in portraiture, in the persons of Mr. Marcus Adams and Mr. F. C. Tilney, enter their protests against the very modified approval bestowed upon the portraiture at the exhibitions, they may be said to treat photography as though customers as a whole cared about artistic expression to the extent of being willing or anxious to pay the price for it. We entirely share the opinion of Mr. Tilney that the future of photography lies on the lines of true art, and that training of the mind in receptiveness to art of any kind is a necessary preliminary to real artistic expression in photography. That is all very well, but in the meantime there is the great undiscerning public which puts down its money in order to purchase things which artistically are atrocious—not photographic portraits only, but carpets and wall papers, illustrated

magazines, and music-hall performances. In parenthesis we anticipate the retort that the public does dimly recognise and appreciate what is artistically good in manufactures, books or music. There is, however, little evidence in shops and advertisements of artistic merit determining the saleability of these things even among those to whom price is not the first consideration. Therefore, so far as concerns a great part—much the greater part—of the photographic portraits which are produced, it is a fact that the qualities which earn them the approval of art critics are not the qualities which bring customers to the studio.

Now a change from this state of things can only be one of slow development, in which photographers of all degrees must take a part in two ways. It is necessary that they should cultivate the artistic element in their work and that, at the same time, they should employ any means within their power to elevate the taste of the public. The two things rank fairly equally in importance and should go hand in hand. It cannot be said, as some correspondents have suggested, that portraiture done for the sections of the public which are inappreciative of artistic qualities can, therefore, dispense with those qualities. To take this view is to deny the very considerable, though perhaps minor, improvements from the artistic standpoint, which are evident in even "cheap" portraits at the present time, compared with those of ten or fifteen years ago. So far as characterisation and artistic expression are concerned there is not perhaps much reason for congratulation, but the signs of a higher æsthetic standard on the part of photographers and of those who purchase their work are provided in a number of lesser features, such as the surfaces and colours of prints, styles of mounting, the disappearance of the hideously artificial backgrounds and accessories, and also the more tasteful arrangement and furnishing of studio premises. In these respects, which are not to be despised, we have moved from a state to which we shall never return; and the comparatively few photographers who have not moved with the spirit of the times in these things provide a measure of the movement from the fact that they are regarded as "back numbers."

But, after all, these amount to very little in raising photographic portraiture to the rank of art which it should and, one day, must generally hold. In contributing to its more rapid advancement to this end, photographers—each one individually—must seek to link themselves more closely with the aims of artists in whatever medium—painting, sculpture, music, or letters. The word "culture" has not gained much in value from the use made of it by our ex-enemies, but in its English sense it stands for the diversity of interests and qualities in which portrait photographers require to be sharers if their craft and business is to obtain the status that is within its reach. In plain words, besides taking and developing negatives and making prints (as much as doing these things), it is the business of the portrait photographer to cultivate an individual delight in what is beautiful, and to use every little step which he may make along this road in contributing to a like appreciation in the minds of the public within his sphere of influence. And the latter is not to be set aside as negligible. In most towns, the two classes of shops where the passers-by in the streets may expect to see art represented in some form or another, are those of the photographers and the print-sellers, yet it is not too much to say that from this point of view the windows of the drapers and the furniture dealers often provide a more satisfactory display. Here, obviously, is one direction in which a photographer can do himself good and, at the same time, contribute to the progress of his profession as a whole. In regard to the question which was raised by our correspondents, namely, the exhibition of examples of portraiture of a more "art" character than the average taste of the public, our own view is diametrically opposed to that which holds that the exhibition of such work is without effect. We are convinced that though the public taste in artistic matters is not refined or discriminating, yet it is amply sufficient to recognise the ability to produce work which may perhaps be above its own standards of preference. And from that admission, it follows as a matter of commonsense that the public will value at a higher rate the services of a man which it seeks for its own purposes. Could there be a more desirable form of linkage between art and commerce? Therefore, in our judgment, it is an entire mistake for a man capable of producing portraits, such as those in the exhibitions, to refrain from showing them to his customers; and we would go further and lay down the general proposition that it is a good policy on the part of the photographer to show not only the best that he can do, but also the works which he personally likes best. How many photographers, we wonder, are at the pains to let their choice in the purchase of a painting, engraving, etching, or articles of artistic craftsmanship, such as bronzes, be known to their customers by the exhibition of these possessions? Yet it is surely a platitude to say that the photographer has a great deal to gain by obtaining recognition as a discriminating lover of the arts, even if he cannot aspire to be a connoisseur.

"Flurographs": An X-ray Innovation.—While experimenting in an effort to make X-ray negatives of documents, Dr. J. A. van Brakle, of Portland (U.S.A.), made a discovery, the product of which he calls "flurographs." Writing on the subject in the "Scientific American," he says: "The original negatives were made by placing the cheque or other document between two fluorescent screens while in contact with an unexposed X-ray film. An X-ray exposure of this combination which was tightly clamped in a light-proof cassette, was then made with the resulting negatives. Development of the exposed film was the routine development for X-ray exposures as made in the medical laboratory.

"At first it was thought that a true radiograph had been made of the exposed document, but further experiment demonstrated that the best negatives were made by means of an X-ray exposure entirely too intense and penetrating for such a slight object as a sheet of paper. Endeavours to X-ray documents without the use of the double fluorescent screens, which in medical work are used simply to intensify the action of the X-ray and thus shorten the time of exposure, were entirely without result. We finally came to the conclusion that these negatives were produced entirely by the action of the fluorescent light set up in the intensifying screens which were in turn activated by the recognised action of the X-rays upon their structure.

"Blurring of certain portions of the samples submitted is due to our inability as yet to obtain a holding cassette with sufficient compression to secure perfect apposition of the document and the film. Contrast between the paper and the printing can be further intensified by refinement of the technique of X-ray exposure. These films were taken with an exposure of 20 milliamperes, an intensity of current represented by an air spark-gap of 4½ inches, distance of 36 inches and time of ½ second.

"Practical uses of this process may include commercial reproduction of documents and other papers, the detection of changes in cheques and bank notes, and a means of measuring and standardising the fluorescent action of intensifying screens."

AN ENLARGEMENT MASKING DEVICE.

CARDBOARD, glue, and some fabric such as bookbinder's linen is all that is required to make a device that will give enlargements with perfectly rectangular masked edges. Enlargements made on card-thickness bromide with the image masked in the centre to show a clear margin of some inches make an attractive "line," and if sent out in an art-paper folder will save the cost of mounting and cardboard. The mask can also be used for the production of enlargements with just a bare margin of white around the picture, which, when trimmed neatly, gives the production a finished appearence.

The device is like the covers of a book (fig. 1), and when closed and the hinged flap folded over the back (fig. 2), presses the mask opening squarely upon the paper in intimate contact with the sensitive paper. It will be noticed that the mask opening is built up and not cut out, and I think this method is easier and infinitely

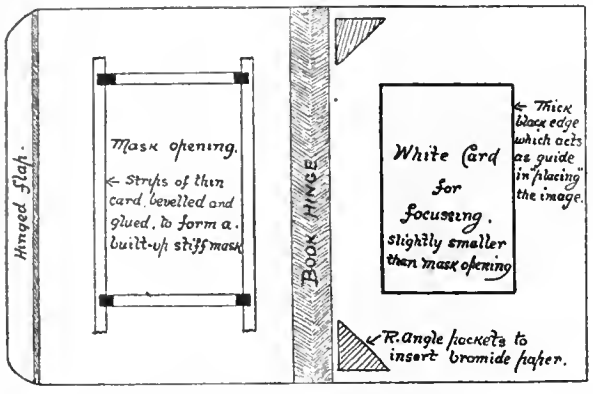

Fig. 1.—Enlargement mask, open.

better than the tricky cut-out which few photographers can do really well. The opening is built up from strips of hard thin card, bevelled, and the focussing is done upon a piece of white card glued to the inside back of the device. This white

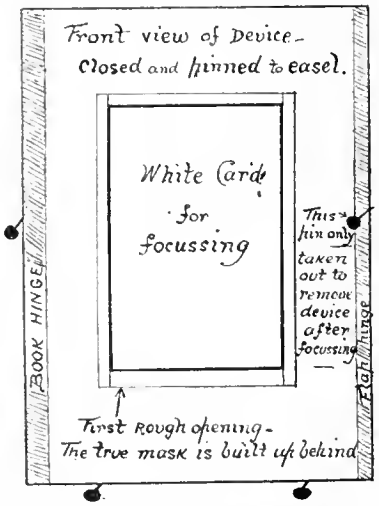

Fig. 2.—Enlargement mask, closed.

card is a trifle smaller than the opening of the mask and acts like the templet of a plate-marker by pushing the sensitive paper into perfect contact with the edges of the mask opening.

Making the Masked Opening.

Take two pieces of 8 to 12-sheet cardboard and cut them together about one inch larger both ways than the particular size of the enlarging paper. This forms the two covers of the "book." On one of the pieces plot out the size of the mask opening by means of a set square and rule, and proceed to cut out an opening about a quarter of an inch *larger* all round than the actual mask opening. This cut-out can be quite roughly done as the mask opening is built up behind the rough opening. Cut some strips of thin card about one inch wide and bevel one edge on the beveller, or cut them to a slight bevel with a sharp knife and straight-edge. Glue one length first to the back of the rough opening so that it overlaps the rough opening by about ¼ inch, bevelled side down. Next cut a piece of thin white cardboard the *exact* size of the actual mask opening, and see that it is perfectly rectangular; then place this piece of cardboard against the first attached strip to act as a guide in fixing the other three strips in position. The other length strip should be fixed next, followed by the two width strips, which must be measured off and cut neatly to fit. If any light leaks through the joins a piece of black paper glued across the joins will soon stop this.

Hinging the Covers.

The next step is to hinge the covers together. Dark-room lamp fabric answers well, but bookbinder's linen is preferable. There are two cover hinges, one inside and one outside, and it is best to fix the inside hinge first in the following way:—Stretch a piece of thin medium parcel twine on the work-bench, pin it down at both ends, push the edge of the *back* cover up to the string at one side and the edge of the front cover to the other side. This is to ensure an even tiny space between the covers (a floating hinge) so that the "book" is flat when closed. Next glue the strip of linen and fix in position with an even margin on both sides of the covers. Now glue another strip of linen to form the back or outside hinge and fix it by closing the "book," pressing the edges upon the glued linen and allowing it to adhere. Then pick up the "book" and firmly press the linen in contact.

The Focussing Card.

The focussing card can now be fixed to the inside back cover. The piece of white card previously cut as a guide for building up the mask opening should be trimmed about 1-16 inch smaller all round, glued, and fixed accurately by closing the book and placing the card in the opening of the mask so that about 1-16 inch margin in shown all round. The whole book should now be well pressed in a cold dry-mounter or press to ensure perfect adhesion. This focussing card should have a black edge around it to facilitate placing of the image, and this is done by ruling a thick black line about 1-16 inch wide close up to the card.

The Side Flap.

This flap can be made of thin card and hinged as shown. The width of the space between the edge of the front card and the edge of the side flap is governed by the thickness of the closed book. The flap is an essential part of the device as it folds over the back cover and clamps the two covers together, thus ensuring perfect contact between the sensitive paper and the mask opening. It also means that only one pin is required to keep this side of the book flat.

The Feed Pockets.

The last stage is to make the "feed" pockets to hold the sensitive paper in position when loading. Very thin linen,

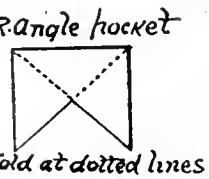

Fig. 3.—Feed pocket.

or leatherette, is best, and can be made as shown in fig. 3 and glued to the inside back cover. These pockets can be dispensed with if desired, and a series of black guide lines can

be drawn upon the inside back cover to act as "feed" marks for whatever sizes of paper are used.

The Device in Use.

The image is roughly focussed upon the easel as usual, and the closed device (empty) placed in position and fixed either by pins as shown, or by other means. The pins most suitable are the steel 2-inch glass-headed variety, and are inserted in the easel at an angle so that the book not only rests upon the pins, but is kept flat against the easel. Fine focussing is then done and the device removed for "loading" by withdrawing one pin only as shown. To load the device, open it and place the bromide paper in the pockets (or to the guide lines) coated side up, close the book and replace on the easel.

R. R. Rawkins.

SCALE OF OPTICAL REPRODUCTION.

[The arithmetical calculations relating to the size of the image formed by a lens are among those which have frequently to be made in such diverse branches of photographic work as, for example, copying and enlarging, aerial photography, and lantern and cinematograph projection. The following article deals with this subject. The present chapter adopts the Gauss conception of the action of a lens as a simple method for derivation of the rules of optical image formation. It considers in particular the case of objects at a distance which is great relatively to the focal length of the lens, thereby emphasising the disturbing effect of depth of focus on certain scale calculations. It also presents the rule determining the relative exposures for different scales of reduction or enlargement. In Part II., to appear in a subsequent issue, the formulæ and rules contained in the present chapter are arranged in a form corresponding with the various conditions occurring in practice, with examples of their use.—Eds. "B.J."]

PART I. *(continued).*

Extra-Focal Distances.

As is seen from formulæ (*b*) and (*c*), calculations involving the focal length f of the lens become simpler by reckoning the distance of the object or the image from the front or rear focal point respectively. These distances, which are therefore u-f and v-f, are the *extra-focal distances* of object and image, and are denoted here by E_u and E_v. Therefore,

$$E_v = v - f = fR$$

$$E_u = u - f = \frac{f}{R}$$

That is to say, the extra-focal image distance is equal to the focal length of the lens multiplied by the ratio of image to object; whilst the extra-focal object distance is equal to the focal length divided by the ratio of image to object. Examples of the usefulness of this simple rule in practical calculations will be given later.

Image-to-Object Distance.

In fig. 3 the distance between the image and the object is denoted by D. It is seen to be equal to $u + v +$ the distance between the nodes, or *nodal space*. For many practical purposes the nodal space is insignificant in comparison with u and v, and can be neglected. The fact that it is neglected in formulæ which follow is indicated by the black patch interpolated in the dimension of D.

A ready means of keeping in mind the relations between the focal length and the distances of object and image from the lens in reproduction on any scale is to think of the distance, D, from object to image as always composed of five distances end on end (see fig. 3). These are:—

1. Focal length multiplied by number of times of reduction or enlargement...	On one side of the lens.
2. One focal length	
3. The nodal space—almost always negligible.	
4. One focal length	On the other side of the lens.
5. Focal length divided by number of times of reduction or enlargement ...	

In the case of reduction, (1) and (2) are on the object side of the lens. In the case of enlargement, (5) and (4) are on the object side of the lens. In the case of same-size reproduction, (1) and (5) become each equal to the focal length, the whole distance from object to image (not reckoning the nodal space) being then four focal lengths. Almost any required calculation relating to the sizes and distances of object and image may be worked out from the first principles embodied in the above easily remembered schedule.

Having now arrived at the fundamental formulæ concerned in the reproduction of objects on any scale of reduction or enlargement, and before setting down the variations in them which are of service, we must refer to the special case which is sometimes the cause of misapprehension.

Scale with Lenses of Different Focal Length.

It is sometimes stated, usually in reference to distant objects, that the scale of reproduction is proportional to the focal length of the lens, for example that a 12-inch lens gives twice as large an image as a 6-inch. From formula (*b*) it is plain that theoretically this is never absolutely the case unless

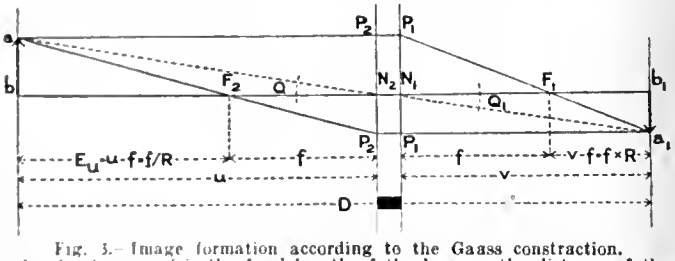

Fig. 3.—Image formation according to the Gauss construction.
In the diagram f is the focal length of the lens; u, the distance of the object, or object conjugate distance; v, the distance of the image, or image conjugate distance. D is the image-to-object distance less the nodal space shown as ■.

the distance of the object is reckoned from the front focal point. At comparatively close distances, the difference between u and $u-f$ considerably modifies the scale of reproduction. For example, when reproducing an object at 6 ft. distance with a 6-inch lens, the scale by formula (*b*) is—

$$\frac{6}{72-6} = \frac{1}{11}$$

whilst with a 12-inch lens the scale is not exactly double, but is

$$\frac{12}{72-12} = \frac{1}{5}$$

It, however, the object distance u is very great relatively to the focal length f, the scale of reproduction, though never absolutely proportional to the focal length, is so nearly so that the error may be neglected. For example, in photographing an object 2,000 ft. distant with a 20-inch lens the size of image (from formula *b*) is 1-1199th (=2-2398ths) the size of the object, whilst with a 10-inch lens it is 1-2399th. If the object measured 200 ft., the size of the images in the two cases would be:—

20-inch lens.	10-inch lens.
2.0017 in.	1.0004 in. $= \frac{2.0008}{2}$ in.

The image with the 20-inch lens is therefore twice the size of that with the 10-inch within an error of .0009 of an inch,

say, 1-1000th of an inch (= 1 per cent. of the size of the image), a negligible amount for almost every purpose for which photographs are taken.

Hence it is evident that in the case of objects which are not nearer to the camera than a certain great multiple of the focal length, the scale of reproduction is equal (with sufficient accuracy, according to the value of the multiple) to the ratio of the focal length to the distance of the object. In other words, within the prescribed limit, the size of the image is directly and separately proportional to the focal length of the lens and inversely and separately proportional to the distance of the object. The case is that of photographing exceedingly distant objects, e.g., in aerial photography, and therefore may be examined a little further in order to ascertain how near the object may be and the size of its image still be proportional to the focal length of the lens.

Also it follows that if, under these conditions, the scale of reproduction is f/u, the camera extension v (formula a) remains the same and is equal to f when photographing objects at various great distances, and therefore formula (c) and others to be given in Part II. containing v cease to apply.

Scale, Focal Length and Depth of Focus.

One way to look at this question is that so long as the camera extensions v remain equal to the respective focal lengths f of the lenses, the scales of reproduction, when employing a series of lenses, are proportional to the focal lengths. Thus, although depth of field theoretically has nothing whatever to do with the scale of reproduction, it does in fact, enter into the question in so far as objects at different distances may be obtained in sharp focus with the lens, or rather its node of emergence, at the distance of the focal length f from the plate. The degree to which the object may be allowed to approach the plate without requiring the latter to be moved from the position of the rear focus will obviously depend upon the aperture of the lens. From the depth standpoint, it can be shown that the minimum object distance beyond which scale is proportional to focal length of lens is, in fact, the so-called hyperfocal distance, *i.e.*, the nearest distance of an object which is obtained sharp when the lens is in focus on "infinity." According to the usual formula this distance is:—

$$\frac{f^2}{FN^0}\times\frac{1}{c}$$

where c is the permissible diameter of the circle of confusion, e.g., 1-100th or 1-250th of an inch, according to the standard of sharpness of definition adopted*.

Hence it is clear that from this standpoint, which is the one corresponding with the use of a camera at "fixed focus," as for example in aerial photography, the fact of depth of focus alters the assumptions upon which formula (c) rests. Owing to depth $v=f$ (that is, $v-f=o$), and thus the formula (c) assumes the form corresponding with the truly infinitely distant object, whilst actually the object is at not such an enormous distance and, if the depth of field is greatly increased by stopping down the lens, may be fairly close. Therefore, under such conditions calculations relating to the scale of reproduction require to be made by means of formula (b). Formula (c) is of value in calculations relating to enlargement or projection.

Scale Calculations and Admissible Error in Size of Image.

But putting aside depth of field as a factor, that is to say, regarding the lens as having no depth of field and therefore requiring a different camera extension for every different distance of object, the problem may be considered from the point of view of the error tolerated in an image. If such admissible error is, say, 1 in 1,000 (0.1 per cent.), then it follows from formula (b) that the distance of the object must be at least 1,000 times the focal length of the lens. For example, in using several lenses of, say, 10, 20 and 36 inches focal length, the sizes of the images produced by them will be proportional to the focal lengths within 1 in 1,000, provided the object is not nearer than 1,000 times the focal length of the longest under comparison, *e.g.*, 1,000 times 36 inches = 1,000 yds.

Generally, if the distance u of the object is n times the focal length f of the lens, the size of the image, according to the assumption that the image is proportional to the focal length and inversely proportional to the distance, is too small by the amount of $1/n$th of its *true size**.

This may be put in a slightly different form which also holds good in all cases. If an object is at a distance u equal n times the focal length f the expression

$$\text{Size of object}\times\frac{f}{u}$$

gives a value for the size of the image which is less than the true size. The value requires to be larger by $\frac{1}{n-1}$th of the image according to the *approximate* rule. For example, if the distance is 100 times the focal length ($n=100$) the size of image by the approximate formula is too small by 1-99th of its size.

These rules therefore provide the means (on the basis of the accuracy of scale required and leaving depth of focus out of consideration) of deciding what is the minimum distance of an object in order that a series of lenses may yield images of sizes proportional to their focal lengths.

The foregoing considerations (from the point of view of depth or accuracy of scale) apply to formulæ Nos. 3, 6, 11 and 12 to be given in the second part of this article. They also apply to the case when the distance of the lens from the *object* becomes practically equal to the focal length of the lens, viz., in reproduction on a great scale of enlargement. Projection with the optical and, particularly, the cinematograph lantern is the only operation of this kind which commonly occurs in practice, the scales of enlargement being respectively about 60 and 180 times. As the image distance is always ascertainable in these circumstances, calculations are made with it as the basis, and therefore it is not necessary to refer further to the effect of depth in this case. The reader will, however, see that for the reasons already mentioned formulæ Nos. 2, 5 and 9 in the next section, namely, those containing the object-distance, cease to be of service in calculations involving a high scale of magnification.

Depth of Definition, Scale and Angle of View.

If a very small stop is used in the lens, the convergent pencils of light which form the image are made very narrow. The angle of each pencil at the focus then becomes so small that the plate may be moved a considerable distance in either direction from a position of focus at a large aperture without causing perceptible unsharpness of the image. The lens in these cir-

* According to other views on depth of field, the distance obtained by the above formula may be halved.

* This perhaps is not obvious at a first glance, but will become so by comparing the true size of the image with that obtained by assuming the scale to be proportional to the focal length whatever the distance of the object.

In any circumstances,

$$\text{image}=\text{object}\times\frac{f}{u-f} \quad \text{(formula } b\text{)}$$

Assuming the size of image to be proportional to the focal length for any distance of object,

$$\text{image}=\text{object}\times\frac{f}{u}$$

$$\text{Therefore error}=\text{object}\left(\frac{f}{u-f}-\frac{f}{u}\right)=\text{object}\times\frac{f^2}{(u-f)u}.$$

Admitting an error of 1 in n, error is

$$\text{object}\times\frac{f}{n(u-f)}.$$

Therefore,

$$\frac{f}{n(u-f)}=\frac{f^2}{u(u-f)}$$

whence

$$\frac{f}{u}=\frac{1}{n}$$

that is, $u = n$ times f.

To put this result in words, if you calculate the size of an image on the basis that the image is equal to the size of the object multiplied by the focal length of the lens, and divided by the distance of the object, the calculated size of the image is smaller than the true size of the image. It is smaller by an amount which is exactly the same proportion of its true size as the proportion of the focal length to the distance of the object. Thus, if the focal length is 1-1000th of the distance, the size of image which is calculated in this way is 1-1000th (= .1 per cent.) smaller than the true image—that is, is 999 thousandths (= 99.9 per cent.) of the true size.

cumstances approximates in its action to a pinhole. Advantage can occasionally be taken of this fact in practice. For example, in the use of a folding camera fitted with a 4-inch lens, a picture of a distant object may be obtained on a larger scale by setting the lens front so as to afford an extension of, say, 4½ inches (the position for focus on an object at 3 ft. distance) and stopping down the lens to *f*/32, or *f*/45. On the other hand, when photographing in confined quarters, a greater angle of view may be included (on a reduced scale) by placing the lens, say, 3½ inches from the plate and again obtaining sharp focus by the use of a small stop. In these circumstances the focal length obviously ceases to be a factor in the scale of reproduction; the latter is then simply the ratio of the image distance *v* to the object distance *u* (formula *a*).

Camera Extension. Back Focus.

As already stated, the term "camera extension" will be used in the formulæ and examples to follow as a convenient name for the distance of the image from the exit node in ordinary photography. Since the exit node in most lenses is fairly near to the diaphragm, the actual camera extension (lens flange to focussing screen) is almost always an inch or so less than this distance. If the exit node is well in front of the diaphragm, as it is, for example, in the Aldis lens, the actual extension demanded of the camera is correspondingly less. In photographing very distant objects, the distance from the focussing screen to the exit node is almost exactly the focal length of the lens. The term *back focus*, sometimes found in opticians' catalogues, is usually employed to denote the distance of the hindermost part of the lens mount (the flange or the rear cell) from the focussing screen in these circumstances. While giving an indication which is of practical utility it does not enter into calculations relating to image formation.

Scale of Reproduction and Exposure.

In a previous paper on the speed of a lens ("B.J.," September 16, p. 550) it has been shown that with any lens the intensity or brightness of the image is proportional to the area of the stop and inversely proportional to the distance from the lens to the image, *i.e.*, to $\frac{d^2}{v^2}$. The relative exposure is therefore proportional to $\frac{v^2}{d^2}$. Hence, with a given lens and with the same stop used for successive copying or enlarging operations on different scales the exposures required are proportional to v^2, that is, to the camera extension multiplied by itself.

But, leaving out of consideration the possibility of photographing on different scales (with the same lens) at the same camera extension owing to depth of focus, we have seen that the distance *v* is always equal to the focal length of the lens *plus* the focal length multiplied by the scale of reproduction R, that is, $v = f + f \times R = f(1 + R)$. Therefore the exposures when photographing on different scales are proportional to $f^2 \times (1 + R)^2$. And since f^2 is a common factor as long as the same lens is used, the exposures are proportional to $(R + 1)^2$.

Thus, for example, the relative exposures, with the same lens and stop, when (1) photographing same size and (2) copying-enlarging three diameters are:—

(1) ..... $(1 + 1)^2 = 2^2 = 4$.
(2) ..... $(3 + 1)^2 = 4^2 = 16$.

The exposure when copying-enlarging three diameters requires to be four times that when photographing same size. This rule applies to any scales of enlargement or reduction, but it will be seen that for considerable degrees of reduction R is a correspondingly small fraction, and therefore beyond a certain limit does not appreciably increase the value of $(R + 1)^2$. For example, in photographing on the scales of reduction of one-fifth and one-tenth (= .2 and .1 respectively) the relative exposures are $(1.2)^2$ and $(1.1)^2 = 1.44$ and 1.21 respectively, showing that in photographing to one-fifth scale only about one-sixth more exposure is required than for a copy under similar conditions on a scale of one-tenth. It is therefore unnecessary to make allowances for variations in exposure due to the scale of the image when the degrees of reduction to be compared are greater than about 10. When copying on various scales of enlargement, the variations are, however, considerable.

In practical work, such as copying originals, allowance for the variation of exposure due to the scale of the image is usually made by taking the exposure when copying same size as 1 and expressing the exposures on other scales by proportionate numbers. This table, familiar for many years in the form drawn up by Mr. W. E. Debenham, serves for use with one lens employed with a given actual stop. The following examples of its construction will further illustrate the application of the $(R + 1)^2$ rule already given, and will serve to show the derivation of the rule from the formula connecting the scale of reproduction and the focal length of the lens.

Scale R.	*v* relative camera extension. (*a*)	(*b*)	v^2 (relative exposure).	Relative exposure same size=1.	
1	$f+f$ =	$2f$	$4f^2$	1	1
½	$f+\frac{f}{2}$ =	$\frac{3f}{2}$	$\frac{9f^2}{4}$	$\frac{9}{16}$	.56
⅓	$f+\frac{f}{3}$ =	$\frac{4f}{3}$	$\frac{16f}{9}$	$\frac{16}{36}$	.44
1/10	$f+\frac{f}{10}$ =	$\frac{11f}{10}$	$\frac{121f^2}{100}$	$\frac{121}{400}$	.30
2	$f+2f$ =	$3f$	$9f^2$	$\frac{9}{4}$	2.25
3	$f+3f$ =	$4f$	$16f^2$	4	4
4	$f+4f$ =	$5f$	$25f^2$	$6\frac{1}{4}$	6.25

G. E. B.

(To be continued.)

PHOTOGRAPHS FOR THE ARGENTINE.—According to the daily Press thumb- and finger-prints are to be required from all persons entering the Argentine after the end of this year. Intending passengers are already required to make personal application at one or other of the Consulates in this country, and to supply two small loose unmounted photographs.

BARGAINS IN CHEAPSIDE.—A distinctive publication among catalogues of second-hand apparatus is that just issued by Messrs. Robbins Manistre, The London Camera Exchange, Ltd., 2, Poultry, Cheapside, London, E.C.2, an excellently printed 64-page list which will repay inspection by intending purchasers, professional or amateur. Messrs. Robbins Manistre adopt the slogan "Something you want for something you don't want," in double reference to their large stock of goods and their terms for supply on a part-exchange basis. The list includes full specifications of enlargers, vest-pocket and other small cameras, reflex cameras, folding focal-plane and stereoscopic cameras, as well as a very great variety of hand and stand instruments. Lenses, from the largest to the smallest, by all the leading makers likewise make up a large section of the list. Prices, we are informed (and we see evidence in the list) have been adjusted to come into line with current market values, and commendable emphasis may also be laid on the firm's declared practice of endeavouring to give the most accurate description of the features of each article and also of its condition. We can heartily recommend the list to those looking around to revise or supplement their equipment. The list is sent free on application.

B

AERIAL PHOTOGRAPHY AND PHOTO-TOPOGRAPHY.

The Twenty-fourth Traill-Taylor Memorial Lecture. Delivered by M. L. P. Clerc at the Royal Photographic Society.

(*Continued from page* 672.)

Internal Orientation of the Image.—In the cameras to be used in mapping on a large scale, it is necessary to provide some means indicating on the photograph the intersections of the optical axis by the plane of the image, supposed to be exactly perpendicular to the said axis; this "principal point" is customarily furnished in photo-theodolites by the intersection of two lines, each of which is defined by two points, registered in the image; these points can be the centres of small conical holes in metallic masks, slightly protruding on to the image or images of the exit pupil of the lens projected by auxiliary lenses of a very short focus. In the absence of some registration of the "principal distance," the distance of the exit nodal point from the principal point, it would be necessary to register the number of the apparatus or of the lens, or some specific sign permitting without any doubt the identification of the camera used to get each photograph.

The use of metal sheaths in the changing box of a photographic camera gives no security of the exact location of the plate relatively to the lens; the rebates are frequently warped, and the thickness of the metal is not always the same. For very precise work it would be desirable to provide some firm abutment to the plate itself at the moment of taking the photograph, as is the rule in the building of photo-theodolites, and not to the rebates. The application of this desideratum to a magazine is obviously a mechanical complication; a somewhat analogous device was used formerly for another purpose by a German maker established in France, Mackenstein ("Bull. Soc. Fr. Photo." [2], vol. 19, August 15, 1903, p. 392).

External Orientation of the Image.—Long before the war the first experimenters in aerial photography attempted to register on each image some of the necessary data to define the location of the plate relatively to the ground at the instant when the photograph was taken. Readings of a compass, of an altimeter, and of various styles of clinometers have been photographed on a corner of the plate. The effects of inertia, during rapid rotary motions of the aeroplane, are able to falsify the indications of these instruments, but when photographs are taken in regular sequence with sufficient overlap, photographs taken in abnormal conditions are easily detected when proofs printed from the negatives are used to mount a mosaic, such photographs protruding out of the common line of those taken in straight flight.

Clinometers regularly used on some German cameras of Zeiss or Goerz make were founded on gravity and gave the slope of the plate and the angle of the lines of maximum slope with one of the geometric axes of the plate: they were used only for the taking of oblique photographs, but it would be easy to adapt them to vertical photography. Instead of photographing pendulums, a French photographer, Liabeuf, in a field-made clinometer, used two air-bubble levers, the indications of which permit of calculating the same data as above. It would be very desirable that an inclinometer be constructed, founded on gyroscopic stabilisation of the indicator, and some attempts already made in this way will lead, let us hope, to a practical solution of the problem.

Some Plate Cameras.—Whereas the magazines used on French and German cameras are derived from the old Hanau's magazine, used with some little differences on many hand-cameras for amateur or press work, the Gaumont magazine was the only one of this type specially devised for aerial photography.

The magazines used on British cameras (Thornton Pickard), and some French ones built in the field by some experimenters (Boulanger, etc.), seem to proceed from the idea of a German inventor, Th. Bänder, to whom was granted, ten years ago, an English patent (22,533, 1911: "Brit. J. Phot.," vol. 59, 1912, p. 618).

Rotary changing boxes built in France in the last months of the war by De Ram and by Fournieux have some analogies with a device described about twenty years ago by J. A. Pantasso in a French patent (317,959, January 21, 1902).

Let us mention also magazines with two adjacent compartments (Ploeck, Folmer, Chassel, etc.), derived from the old Flo changing box, the Italian Lamperti apparatus, recalling the mechanism of the old detective-cameras, and some ingenious but somewhat intricate plate-changing mechanisms of H. Jacquelin and of R. Aubry.

It was rapidly realised that hand-operated cameras cannot give regularly perfect results without employing very trained operators, who suffer severe strain, and who are prevented from paying sufficient attention to more useful things than the supply of muscular labour.

The first step in the way of a simplification of the working of aerial cameras was the connection between the changing of the plate and the setting of the shutter, as in the E camera of the Royal Flying Corps, or in French cameras built by various experimenters as Boulanger, Borzecki, etc., sometimes also the releasing of the shutter was obtained by the reverse movement of the lever actuating the two other functions, as in the Lamperti apparatus and in those evolved by Jacquelin, Aubry and others; most of these cameras were operated at a distance by Bowden wires.

The second step was the employment of motive power for changing the plate and setting the shutter, the releasing being left at the personal control of the operator; the power can be supplied either by a wind motor or by an electromotor; the use of clockwork is out of the question, the elasticity of the springs being too greatly depressed at low temperatures, and this circumstance is probably the cause of the systematic failures of the Brock camera.

The last step was the complete automatism of the apparatus, some mechanism releasing the shutter at regular intervals, the time elapsing between the taking of two pictures being changeable at the will of the operator, either by speed-reducing gears or friction discs, or by an alteration of the pitch of the propeller, or by varying the supply of air to the wind turbine. Preference is to be given to the less intricate mechanism, all delicate adjustments being inclined to go wrong after some rough landing.

In the last period of the war almost all makers of aerial cameras had solved this problem, but these automatic cameras were delivered too late to be effectively used before the cessation of hostilities.

Coupled Cameras.—Long before the war multiple cameras were used to cover at a time, from one standpoint, all visible ground, partly by a vertical camera and partly by a number of oblique cameras symmetrically disposed around the vertical axis of the system. Such a device was necessary for photography from ordinary balloons, without any control on their travel, but has no real advantage for photography from an airship.

But the coupling of several cameras is interesting for another purpose. For precise mapping it is necessary to have at least three photographs of each part of the ground, each taken from a different standpoint: one of them for the verification of the graphic constructions made from the two others. The easiest way to get these three sets of photographs is to use three cameras, suitably coupled and simultaneously released; the axis of one of these cameras must be vertical, the two others being located in two rectangular vertical planes containing also the axis of the vertical camera, the angle of these axes with the vertical being about 30 degrees. In such conditions, the three lines of which the common intersection will give a point on the map cross at an angle of from 45 to 90 degrees, the point being perfectly determined.

The experiments actually pursued in France for the cadastral surveying of devastated countries are made on this principle; it is hoped that three automatic cameras, each of them supplied with a magazine for 150 plates 18 by 24 centimetres, will be so coupled for the execution of this work.

Camera Suspension.—While the first cameras used on aeroplanes at the beginning of the war were held by hand outside the fuselage and, afterwards, through an opening in the floor, the extending use of long-focus cameras, heavily loaded with a number of large-size plates, made it necessary to extemporise in the field some means of suspension not provided by the technical services The

most extravagant conceptions were given full vent, and each squadron, or somtimes each observer, had a special model built by the engine-men of the squadron.

An efficient suspension must not only absorb or considerably weaken vibrations of short period, but also subdue and slacken pendular oscil'ations and torsions, this last condition being of particular importance for precise mapping, where it is necessary that the image of a point be a point, and not some element of a line. It is also very desirable that the suspension ensures the verticality of the axis of the camera, or some invariable slope of the said axis. For convenience of installing and to ensure good regulation of the suspension, the camera and its vibration absorbers should be preferably built as a unit, easily fastened to the aeroplane by some bolts or straps and easily removed after each flight, without any intricate adjustments, for which the time allowed is rarely sufficient.

I believe that the British Air Force, and afterwards the American, were the only ones to use a testing method of camera suspension by flying over some intense lights, one of which is periodically interrupted, on a dark background with the lens uncovered, getting thus undulated trails on which can be measured the period and the amplitude of the residual vibrations.

Practical comparisons of the various mountings showed that any rigid mounting is to be avoided and that almost all modes of suspension are efficient if the camera is mounted at its centre of gravity, this condition involving the rejection of all plate cameras in which the changing of plates leads to an appreciable displacement of the centre of gravity.

I mention, as being very convenient, a mounting introduced in the French Army and consisting of four parallel bell cranks, rigidly linked, transforming all shocks into translation movements, deadened by springs, and also the use of conveniently adjusted springs or of tennis balls, rubber sponge, thick felt and similar vibration absorbers. Pendular suspensions and floor mountings have almost always given very bad results. The maintenance of the verticality of the axis could only be ensured by some gyroscopically controlled mounting; some patents have been granted for such devices, but I have not heard of the results so obtained.

Photographic Manipulations.—In addition to the condition of having a high chromatic sensitiveness, the photographic emulsions suitable for aerial photography must possess a high resolving power and be able to be rapidly developed to great contrast, with the minimum of fog. The gelatine used in the preparation of these emulsions must be sufficiently hard to withstand warm solutions and rapid drying.

Desensitisation, according to Luppo-Cramer's process, is very valuable in permitting visual control of the development and keeping the balance between the necessity of sufficient contrast and avoiding that the fog due to atmospheric haze gives a too high density; desensitisation is actually adopted by the French and Japanese Armies.

Experiments made for the United States Air Force at the Eastman Kodak Research Laboratory have shown the perfect suitability of chlorhydroquinone and metol developer, as giving a high value to gamma infinity, a high speed and a very good resolving power; the chlorhydroquinone is, unfortunately, not a regular article of manufacture, and has to be replaced by hydroquinone.

Sensitive papers used for printing or enlarging must be coated with very rapid emulsions of a high gloss, and giving extreme contrasts; the paper must possess a high tensile strength, even in the wet state; the gelatine must be sufficiently hardened to permit of very quick hot drying.

The shrinkage of the paper is a serious objection to the use of paper prints in photo-surveying; experiments made by the French Naval Surveyor, H. Rousilhe, seem to give proof of the suitability of paper prints for very precise work, if the paper is, before any use, wetted until it is fully expanded and then stretched on a stirator board, in which it is left until the completion of the work. The most convenient contrivance for the development of plates is certainly the single plate-holder suggested by E. Cousin, a number of these grooved frames being immersed at a time in a vertical tank, but it is necessary that such pieces are heavily nickel-plated to avoid the effects of chemical fog due to the contact of ordinary developers with copper or tin.

For the developing of films the Eastman Kodak Co. has issued an enlargement of their well-known film tank with a teeth-bordered apron of sufficient length to receive a 75-ft. film.

The distribution of very large issues of a number of aerial negatives in a very short time compelled, during the War, the design of various models of rapid printing boxes; a very ingenious type was that conceived by R. Aubry for the printing on continuous bands of sensitive paper, the printing box being completed by a very simple developing and finishing machine.

I will show on the screen, without any description, the successive models of travelling dark rooms used in the French Air Service.

The Photographic Correction of Negatives taken Obliquely.—I do not intend to repeat here the calculations I have already published in full in the "British Journal of Photography," Vol. 66, 1919, Nos. 3038 to 3091, but only to show, comparatively to the Schweimpflug's Perspectograph, the automatic enlarger-corrector, permitting a variable enlargement, I had devised in the form of a demonstration model; in this apparatus the law of conjugate points is automatically maintained by applying to the two axes of the swinging frames the cinematic connection known as Paucellier's inverter, and the connection of the planes of the two frames is ensured by two arms, each of which is perpendicular to one frame, these two arms crossing themselves in a slot, perpendicular to the optical axis, and constantly maintained by the inverter in a symmetrical position of that of the lens relatively to the middle of the portion of the optical axis bounded by its crossings with the axis of the swinging frames. In this apparatus the use of angular division was avoided by a sine scale.

A non-automtatic correcting camera has been devised by H. Rousilhe and is now being used in France for the preparation of cadastral maps; in this model the rising movement of the lens is replaced by the swinging of the said lens around an axis, cutting the optical axis between the two nodal points; if such swinging of the lens is not objectionable from a strictly mathematical standpoint, on the condition that the lens is of an ideal perfection, it is not certain that in practice it realises an improvement.

The Interpretation of Aerial Photographs.

I will consider only some properties of the shadows and the use of these properties.

First of all, it is important to hold the photograph in the right position to be able to have a correct perception of reliefs and hollows; contrarily to a rule admitted in some French circles, and reproduced in Ives' book, the best position of the photograph is not that in which shadows are falling toward the beholder, but that in which shadows are cast at 45 degrees on the right and the bottom side. I will pass round a photograph of a quarry in which the effect is quite convincing.

If the time at which a vertical photograph was taken is known, it is an easy matter to locate the true north on the photograph; I devised a dial which, when placed on the image, the hour-line being pointed in the direction of the shadows, gave the direction of the north for each period of the year. If, furthermore, the scale of the photograph is known, it is easy to deduce from the length of each shadow the height of the object casting it. I had computed a chart giving for all hours of the day (Greenwich time), and for all periods of the year, the length of the shadow, the height of the object being taken as the unit. This chart, with the corresponding calculations, has been published in the "British Journal of Photography" (May 30, 1919); it was also reproduced, with the above-mentioned dial, in Ives' "Aeroplane Photography," without any mention of their source.

Photo-topography.

Mosaic Mapping.—An aerial photograph, even if taken with a camera, the axis of which was perfectly vertical, or corrected to compensate for any inclination of the axis, is never coincident with a map, unless the ground be perfectly horizontal, a rarely satisfied condition. The photograph is, in fact, a conical projection, while a large scale map is an orthogonal projection on a plane tangential to the terrestrial sphere. All points of the ground located above the mean plane are projected on the photograph outwards of their true map position, and inversely all points located under the mean plane are photographed inwards of their true position in the map.

It results from this fact that when assembling prints for a mosaic, if the joining of successive photographs is not made along a horizontal line of the ground, the images of some high points are wanting and the images of some low points of the ground are duplicated on either side of the junction.

I should abuse your patience if I attempted to describe the necessary precautions for scaling a sequence of photographs joining two known points in a country of which no map has already been drawn, and also to scale and assemble a series of independent flights, each of them containing the images of at least two apices of the geodesic polygonal groundwork; instructions for this work are given at length in a recent French book by E. de Larminat; let me add that these methods are able only to give approximate maps on a low scale. It would be very desirable, for the making of mosaic maps, to possess a positive emulsion coated on a waterproof paper, to avoid the unequal stretching of the paper according as the measure is parallel or transverse to the fibres. All photographs taken for the building of a provisional mosaic map must be filed to be used for the drawing of a more precise map when a more complete trigonometrical survey will have been done by the classic methods.

Photo-topography.—A precise surveying on a large scale by aerial photography is possible only if the ground is covered by a network sufficiently dense of signals easily perceptible on the photographs, generally white panels symmetrically placed around each land-mark, the co-ordinates of each signal having been ascertained either by the classic methods of surveying or by photogrammetric or stereophotogrammetric methods.

Before using the data supplied by a photograph it is necessary to have ascertained the external orientation of the image, that is to say, to know the base on the ground of the vertical drawn from the standpoint, the height of this standpoint above the sea-level, and the intersection of the optical axis by the horizontal reference plane when the said photograph was taken. This problem can be solved either by graphic methods or in a correcting camera, or in a correcting enlarging lantern by successive trials, trying to get the coincidence of the images of at least four signals with the corresponding points of the map, for a first approximation, and with the projections of these signals, from supposed position of the standpoint, on the horizontal plane containing the lowest signal, for each following approximation, the unknown data being deduced from the readings on the various scales of the apparatus.

If one negative does not contain the images of a sufficient number of signals, but if this negative has a sufficient overlap with the adjacent photographs, it is generally possible to choose, in the common part of the two images, a sufficient number of well-identified points in the same plane to be able to get in a correcting camera a transformed image of one of the negatives such as would have been obtained, from the same standpoint, in the plane of the other. The two photographs can then be assembled, and such an assemblage does probably include the necessary number of signals.

This method can be generalised to any number of photographs and would permit the correction of a series of photographs, previously transformed in the plane of one of them, if the whole series contains the images of four known points.

It has been suggested to dispose on the ground a number of signals in great excess of the requirements, and to defer the trigonometric survey of these signals until the photographs have been taken; it is then possible to choose most of the signals in the common parts of successive photographs in order to lessen the necessary number of calculations.

In a paper by Capt. A. Guillemet it has been asserted that in some attempts at cadastral surveying made two years ago near Lagny-sur-Marne with a very imperfect equipment, all points would have been located with an error of less than 8 ins., the map being drawn by the intersection method, and each point being determined by the intersection of three vectors, each supplied by a separate photograph

In Germany, graphic methods seem to have been superseded by actual measurements on the negative, either in a "Komparator" for the measurement of the co-ordinates of each point of the image, or in a "Bildmesstheodolit" for measuring angles as it would be possible to measure them with an ordinary theodolite from the same standpoint from which the photograph was taken. A full description of these apparatus and examples of calculations made from such data are given in Hugershoff and Cranz's book.

Attempts are now being made to use for aerial photo-topography modified models of the "stereocomparator," and of von Orel's "autostéréograph," each negative being presented in such conditions that its angle with the optical axis of the eyepiece is the same as its angle with the vertical when the photograph was taken. It seems difficult to hope for the same degree of precision attained in stereophotogrammetric work from steady standpoints the location of which is perfectly known.

Aerial Stereoscopy.—The stereoscopic examination of aerial photographs has played an important part during the War, both for the interpretation of photographs taken of the trenches or other enemy works, and to get a detailed knowledge of the forms of the ground, not shown by the existing maps, giving an easy means to draw approximately the orography of the maps on a large scale necessary for immediate use. I had the good fortune to be one of the first to try the stereoscopic examination of aerial photographs, and to express the rules which were adopted by the Allied Armies for the taking and the mounting of such stereograms.

Two cases must be considered according as photographs are taken vertically or obliquely. In the first case, all objects are included between two horizontal planes the interval of which is a very small fraction of their distance from the camera; in the second case, the photographs are usually taken at a very moderate height, and the distance of the foreground is often a small fraction of the distance of the background.

In vertical photography (or zenithal photography, as it is sometimes called) it is an easy matter to get a correct representation of the reliefs; using a stereoscope with eyepieces of the same focal length as that of the lens used on the camera, *it suffices that the interval between the standpoints of the two negatives, measured on the common scale of the two photographs, be equal to the mean separation of our eyes.* The use of ordinary stereoscopes, of about 5 ins. focus, reduces the vertical sizes of all objects relatively to their horizontal sizes but without any alteration of the absolute value of the reliefs so perceived; in practice, the use of such stereoscopes is an advantage, due to the magnifying of details by the short-focus eyepieces

I have justified this rule in the book I published two years ago; the slide actually on the screen reproduces one of the panels I used for this demonstration to my military students and shows the various deformations of a cube when the above rule is not complied with; the worst of these deformations is obtained when the separation of the two standpoints is shorter than indicated, because the resolving power of the stereogram (its ability to show faint reliefs) is badly lowered. In oblique photography the experimental rule expressed by L. Cazes in the best study ever published on stereoscopy ("Stéréoscopie de Précision." Paris, 1895) does not give a sufficient sensitiveness at great distances from the base; I have found that in the particular case of aerial stereoscopy, where objects at various distances do not overlap, as in terrestrial photography, but are classified by growing remoteness from the bottom toward the top of the image, the separation of the two standpoints can be five times greater than that recommended by Cazes, being calculated from the condition that the separation of homologous points (the distance of the two images, left and right, of the same point of the ground) does not vary by more than one tenth of the focal length of the eye-pieces of the stereoscope.

The diagrams now on the screen translate in an easily readable form the two rules to be applied respectively to vertical and to oblique aerial stereoscopy; this chart was issued during the War in the form of blue-prints which were largely distributed to those interested in this question; it is reproduced in my book, and the diagram for vertical stereoscopy has also been reproduced in Ives' book, but after my signature was erased.

I believe it is necessary to point out that the forms suggested by an aerial stereogram can be largely different from the real forms if, when taking the two photographs, the optical axes are not exactly parallel, and their common direction exactly perpendicular to the line joining the two standpoints; unless the photographs be corrected before they are used in the mounting of the stereogram, the transgression of this rule will transform planes into cylinders of circular, elliptic or paraholic curvature; long after I had studied these deformations, and proceeding to bibliographical researches, I found that the same problem had been discussed between these walls by Lyndon Bolton ("Photographic Journal," Vol. 43, 1903, pp. 107-118) and elsewhere by German mathematicians.

I will not lengthen an already too long paper by discussing practical rules for the taking and mounting of aerial stereograms, and I prefer to show you some results, using some anaglyphic slides obtained by Mr. L. Gimpel, who has recently described his procedure ("Bull. Soc. Fr. Phot." [3], vol. 8, 1921, pp. 194-204).

L. P. Clerc.

FORTHCOMING EXHIBITIONS.

November 17 to 19.—Bowes Park and District Photographic Society. Particulars from the Hon. Sec., S. Smith, 68, Mannock Road, Wood Green, London, N.22.

November 23 to 26.—Rotherham Photographic Society. Particulars and entry forms from the Hon. Exhibition Secretary, Sydney G. Liversidge, "Orissa," Gerard Road, Rotherham

December 3 to 17.—Scottish Photographic Circle. Hon. Secretary, W. S. Crocket, 10, Parkgrove Terrace, Tollcross, Glasgow.

1922.

January 21 to February 4.—Partick Camera Club. Latest date for entries, January 30. Particulars from the Hon. Secretary, James Whyte, 51a, Peel Street, Partick Glasgow.

February 11 to 25.—Scottish Photographic Salon. Particulars from the Secretary, James F. Smellie, Braefindon, Allanshaw Street, Hamilton.

February 14 to 17.—Exeter Camera Club. Particulars from C. Beauchamp Hall, Hon. Exhibition Secretary, Exeter Camera Club, "St. Denys," Bellevue Road, Exmouth.

Patent News.

Process patents applications and specifications—are treated in "Photo-Mechanical Notes."

Applications, October 31 to November 5:—

STENCILS.—No. 28,982. Photographic stencils, and method for making. J. D. Coe.

CAMERAS.—No. 28,875. Cameras. F. W. Flood and M. B. Sheridan.

VESSELS.—No. 29,360. Vessel for photogeaphic processes. A R. Sammeregill.

COMPLETE SPECIFICATIONS ACCEPTED.

These specifications are obtainable, price 1/- each, post free, from the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C.

The date in brackets is that of application in this country; or abroad, in the case of patents granted under the International Convention.

OZOBROME PROCESS.—No 148,462 (June 16, 1919). In practical operation it has been found advisable, in order to facilitate the development of the medium tones, to add alum to the bath in which the carbon tissue is to be immersed before applying the same upon the original print. But in this bath the alum causes the formation of insoluble precipitates which are deposited and whereby the bath is weakened, so that it becomes impossible to obtain successive prints of uniform character, save by adding to the bath the proper amount of those constituents which become weakened.

In order to obviate these drawbacks, and to obtain the pigment-coloured images with their relative values in the half tones, the invention consists in previously preparing the tissues by immersion in an ozobrome bath containing no alum. After drying, these papers are preserved in a dry place, and, upon using the same, it is only required to immerse them in water or in a solution of one of the constituents of the ozobrome bath before applying them in the usual manner upon the original print.

In this manner a new product is obtained, consisting of a tissue which is impregnated with the reagents constituting the ozobrome bath, no alum being used. The paper is dried and can be kept, and when required for use is immersed in water or in a solution of one of the constituents employed for the previous impregnation.

The pigmented paper is immersed in a complete solution which does not contain alum, that is to say, in a bath containing the following:—bichromate of potassium, ferricyanide of potassium, and bromide of potassium, and the paper is dried, and when required for use is immersed in water or in a solution of one of the above ingredients. Alternatively, one of the constituents of the solution may be omitted, for example, the bichromate of potassium, which consequently gives for the composition of the bath in which the paper is to be impregnated: ferricyanide of potassium and bromide of potassium.

In such alternative the paper is prepared for use by immersing it in a solution of the constituent which has not been utilised to obtain the previous impregnating solution, that is to say, in the above particular example, in the bichromate of potassium. This method of previous impregnation can be employed at the present time whatever may be the composition of the coated paper.

Instead of preparing the paper by using as a base a coated paper of a current type which is immersed in the bath as described, the paper according to the invention can be prepared by employing an ozobrome bath without alum and mixing therewith the colouring matter, the mucilaginous substances forming the support and the usual products contained in the coated paper. This composition is then coated upon the paper according to the well-known methods. The mucilaginous gelatine can be replaced by albumen, gum or other suitable mucilaginous substances, while the pigments can be constituted by inert colouring matter in powdered form other than carbon.

Instead of employing as in the usual methods a paper containing colouring matter which is to be immersed in the ozobrome bath immediately before the said paper is applied upon the silver print, which gives uncertain results and a lack of uniformity in the prints obtained, in the process according to the invention a paper is produced containing the colouring matter together with constituents of the ozobrome bath, which can be kept in the same manner as an ordinary paper containing silver salts.—Louis Ratier, Rue Lallier, Paris.

SILHOUETTE PHOTOGRAPHS.—No. 147,621 (July 8, 1920). The invention is a modification of the process described in Specification No. 169,233 ("B.J.", October 28, 1921, p. 647). One filter only may be used instead of two or the same result may be attained without any filter at all. Using, for example, a yellow background the first picture may be taken with a yellow filter upon an orthochromatic plate or film. In this case the background will appear opaque, that is, so much of the coating as is occupied by the background will, after development, appear on the negative as covered. The second view is taken on an ordinary plate or film which is under normal conditions almost insensitive for yellow, and in the negative the background will be transparent. On the print the background will thus in the first case become white, in the second case black. If an emulsion which is specially sensitised for yellow is used for the first picture, there is no necessity of employing a filter in either case.

Similar conditions exist for backgrounds of other colours. In the case of a blue background, for instance, the first picture may be taken with an ordinary plate or film, because its coating is, as is generally known, highly sensitive for blue, and, accordingly, the blue background will come out opaque. For the second picture an orthochromatic plate may be taken, the sensitiveness of which for blue is perfectly neutralised by a spectroscopically suited yellow filter, so that the background appears transparent, or a plate may be employed which has been rendered insensitive for blue by an impregnation with dianil red. In the former case only one filter is required for screening the blue rays, while in the second case no filter at all is required.—Hans Goetz, 1, Sendlingertorplatz, Munich, Germany.

Trade Names and Marks.

APPLICATIONS FOR REGISTRATION.

NOVEX. No. 418,671. Chemical substances used in photography, photographic plates and photographic films. Kosmos Photographics, Ltd., Balfour House, Finsbury Pavement, London, E.C.2, and Pixmore Avenue, Letchworth, Hertfordshire, manufacturers. September 20, 1921.

WELLINGTON (CHILD DESIGN).—No. 412,403. Photographic paper. Wellington and Ward, Shenley Road, Boreham Wood, Elstree, Hertfordshire, manufacturers. February 11, 1921.

MESSRS. WITT AND WESTLEY, manufacturers of photographic mounts, advise of their change of address from Finsbury Park to 13, Bishop's Court, Holborn, E.C.4, where their telephone number is Holborn 2094.

LITERATURE OF AERIAL PHOTOGRAPHY.—M. L. P Clerc appended to his Traill-Taylor lecture (the concluding portion of which appears in this issue) a valuable list of the articles, papers, books and patent specifications relating to aerial photography and photo-surveying. We hope to publish it in a later issue.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

Monday, November 21.

Birmingham Photographic Art Club. "Bromoil" Demonstration. H. J. Shepherd.
Bowes Park and District Phot. Soc. "Flashlight Portraiture." Messrs. Johnson.
Bradford P.S. "Bromoil for Beginners." W. E. Gundill.
Dewsbury P.S. "North-East Yorkshire." S. Guy.

ROYAL PHOTOGRAPHIC SOCIETY.

Meeting held Tuesday, November 15, the president, Dr. G. H. Rodman in the chair.

A lantern lecture, "Some Sea Birds," was delivered by Mr. F. R. D. Onslow, and dealt in a most interesting manner with the author's experiences as a photographer of marine birds. A large number of lantern illustrations showed the range of his work in this field. The hearty thanks of the meeting to Mr. Onslow were accorded

CROYDON CAMERA CLUB.

"Another of those rotten 'print displays' for next Wednesday," disgustedly exclaimed a worthy medical member whilst perusing the syllabus the previous week. He had evidently forgotten that photographic societies have as the reason, or excuse, for their existence the production of photographs, including, of course, every step necessary to the attainment of that object. With old members, who have seen many house exhibitions, all much of a muchness, and listened to more or less, stereotyped criticisms year in and year out, the appeal of such evenings must certainly tend to diminish with time. On the other hand, a few veterans appear to preserve an unabated interest, and the enthusiasm of the younger generation of pictorialists should make ample amends for any feeling of boredom experienced by some. Last week the "print display" comprised few exhibits, but of excellent quality. The fog prevailing doubtless prevented many members from arriving with masterpieces under their arms.

During the evening Mr. A. E. Issac showed an "Osglim" lamp of the General Electric Co. As the name suggests, it is of very low candle-power, and, indeed, may be regarded as an electric night-light. He suggested its use for a dark-lamp illuminant. A rare gas "Neon" glows orange between two electrodes contained in the bulb, and the life is far longer than that of a filament lamp. The consumption of current is only five watts (about one-fourth the lowest limit of filament lamps of the same voltage), and lamps are supplied for direct and alternating current at voltages 200 to 250. In cases where a small light is required continuously the "Osglim" lamp, in his opinion, seems just the thing. Another type is used for advertisement purposes, the cathode being shaped to various letters of the alphabet.

Mr. E. A. Salt said the lamp was very interesting, as many electricians thought that the electric light of the future would be on similar lines—the production of light without heat. The "Moore tube" is another example of gas being made to glow electrically, but the voltage required is very high and secured by a high-tension transformer. Such a tube can be run round the walls of a room, and careful provision has been made to safeguard against accident. A peculiar property of Neon gas is that it permits of the passage of the electric discharge at a comparatively low voltage. Although the light is of orange hue it is also rich in ultra-violet, an undesirable feature for a dark-lamp illuminant. A carbon (not a metallic) filament lamp, he said, is best for this purpose.

Among other cheerful items of the evening, which included the return of a valued old member, Mr. W. H. Smith, a set of photographs illustrating ruptures of the membranes of the brain was shown by Mr L. J. Hibbert. Owing to a slight misunderstanding sincere wishes were expressed for his speedy recovery

---

EDINBURGH SOCIETY OF PROFESSIONAL PHOTOGRAPHERS.

Meeting held, Monday, November 7. Present: Messrs. MacKay, Moffat, Campbell Harper, Johnston, Fergusson, Laing, Norman Thomson, John Thomson, E. D. Young, George Balmain, W. J. Hutcheson, C. D. Crooke and Philip. Mr. Campbell Harper, the president, in the chair.

The President explained that at a meeting of the council of the Society it was unanimously resolved to send the congratulations of the members to Mr. Wm. Crooke, Princes Street, Edinburgh, one of their members, on the success which he had achieved at the exhibitions in America, and on the unique and distinguished honours which had been meritoriously awarded to him in that country. It was also agreed to invite him as a guest of the Society to the annual dinner in December. The Secretary read the letter addressed by him to Mr. Crooke, and Mr. Crooke's reply, thanking the members for their congratulations and accepting the invitation to dinner.

Mr. E. D. Young reported that in response to the circular sent out to the members he had an addition of three or four pupils to the drawing and retouching class at the College of Art. He thought if other six pupils joined that would assure the success of the

class and warrant the College authorities to continue it. The President pointed out the trouble which the Society had in getting this class started, and urged members to get as many as possible of their assistants to attend.

The annual dinner of the Society was fixed for Monday, December 5, at Messrs. Fergnson and Forrester's Restaurant, Princes Street. Messrs. Campbell Harper, Fergusson, Young, Moffat, Geo. Balmain and Philip were appointed a committee to carry out the arrangements.

The discussion on the minimum prices of commercial photographs was postponed to a further meeting, when it was hoped Mr. Hislop would be able to attend. It was unanimously agreed to invite Mr. Hislop to become a member of the Society.

The President mentioned that Mr. Crowther, of Messrs Marion, London, was giving a lecture to the Glasgow Society early next month, and that if an invitation was extended to him he would be pleased to come to Edinburgh and deliver one to the Society. It was agreed to invite Mr. Crowther.

Mr. Moffat mentioned that he had been approached by Mr. Turnbull, 20, Hillside Street, Edinburgh, the owner of a neat delivery van, offering to deliver photographers' parcels at the rate of 25s. per week, or 5d. each parcel. He thought that the proposal was a good one, and commended it to the members for their consideration.

A vote of thanks to the President concluded the meeting.

Commercial & Legal Intelligence.

Legal Notices.—Notice is given, pursuant to Section 242 (3) of the Companies (Consolidation) Act, 1908, that at the expiration of three months from November 11, 1921, the name of the Photographic Art Development Company, Ltd., will, unless cause is shown to the contrary, be struck off the Register of Joint Stock Companies, and the company will be dissolved.

Notice has been given that a petition for the winding-up of the Arundel Studio, Ltd., has been presented to the High Court of Justice by the Art Reproduction Company, Ltd., of 3-4, Plough Court, Fetter Lane, E.C., engravers and printers, a creditor of the company. The petition will be heard at the Royal Courts of Justice, Strand, W.C., on November 22. Any person intending to appear at the hearing of the petition must give written notice on or before November 21 to Arthur Benjamin and Cohen, 23, College Hill, E.C.4, solicitors, for the petitioners.

At a recent extraordinary general meeting of the members of the Langham Studio, Ltd., held at the offices of Messrs. Edward Moore & Sons, 3, Crosby Square, E.C.3, a resolution was passed to the effect, that the company be wound up voluntarily, and that Kenneth Alfred Edgar Moore, of 3, Crosby Square, E.C., be appointed liquidator. Notice is given, pursuant to Section 188 of the Companies (Consolidation) Act, 1908, that a meeting of creditors will be held at the above address on November 23, at 3 p.m., for the purposes provided in the said section.

Notice is given of the dissolution, by mutual consent, of the following partnerships:—(1) Between David Samuel Childs and Herbert Rowe, carrying on business as process engravers, at 20-21, Bride Lane, London, E.C.4, under the style of Childs & Rowe. All debts due to and owing by the late firm will be received and paid by David Samuel Childs. (2) Between Arthur Priestley Boocock and Frank Newsome, carrying on business as photographic publishers, at 178, Garnett Street, Bradford, under the style of The Northern Photographic Co. All debts due to and owing by the late firm will be received and paid by Arthur Priestley Boocock, who will continue to carry on the business.

Eastman Kodak Company.—In addition to the usual quarterly dividends of 1½ per cent. (being at the rate of 6 per cent. per annum) upon the outstanding Preferred Stock, and of 2½ per cent. (being at the rate of 10 per cent. per annum) upon the outstanding Common Stock, the directors have declared an extra dividend of 7½ per cent. upon the Common Stock, all payable on January 2, 1922, to stockholders of record on November 30, 1921.

NEW COMPANIES.

R. F. Hunter, Ltd.—This private company was registered on November 3, with a capital of £3,000 in £1 shares. Objects: To acquire the businesses carried on at 9, Cavendish Circus, Buxton, and 3, The Promenade, Cheltenham, and to carry on the business of photographic chemists, camera and other photographic apparatus manufacturers and dealers, portrait painters, photographers, etc. The subscribers (each with one share) are:—R. F. Hunter, 9, Cavendish Circus, Buxton, Derbyshire, photographer; Mrs. M. M. Hunter, 9, Cavendish Circus, Buxton, Derbyshire; E. Grundy, 22, Booth Street, Manchester, C.A. The first directors are not named.

News and Notes.

View-Stealing in America.—Mr. D. W. Griffith, the well-known film producer is suing the United States Government for spying on his studios from the air. He is taking this action to seek a definite ruling as to the rights of American Army airmen to fly over private property for the purpose of sight-seeing or taking photographs. Prying visitors, many with pocket cameras, have been excluded from the studios, and so aeroplane joy rides to see and photograph set scenes from the air have become popular.

Messrs. Wallace Heaton, Ltd., 84, High St., Sheffield, send us their November sale catalogue of sixty pages, listing 743 lots of apparatus which they are offering at special prices for the purpose of clearing stock. The goods represent leading models of all types of hand and stand cameras, lenses and enlargers, and a considerable variety of optical instruments, including binoculars, telescopes, microscopes, etc. The list contains full particulars of the firm's offer to forward on approval against deposit, or to supply on gradual payment terms, and is obtainable free on application.

The Kosmos Competition.—The list of prize-winners in the competition recently organied by Messrs. Kosmos Photographics, Ltd., has been published, and includes some hundreds of names. The first prize of £100 is gained by Mr. H. Victor Vokes, of Southampton. We are interested to learn that an enormous number of prints were received and that the general high standard of quality, particularly in the more expert classes, made the task of judging a somewhat difficult one. The Kosmos Company observe that the present competition brought in a very much greater number of pictures of real merit and confirms them in their view that very keen interest continues to be taken in serious photography. No doubt this fact will encourage them in the organising of future competitions and in repeating the very generous allocation of numerous consolation prizes.

Aerial Surveying by Photography.—The camera is to be used in order to expedite work on the new London to Southend road, the Ministry of Transport having decided to make a new survey by air of the proposed route between Romford and Prittlewell. The survey will be carried out by three men in about twenty minutes on the first fine day. If the survey of the 21-mile stretch were made under the old conditions it would take a small army of men several days.

An official of Aerofilms, Ltd., who will undertake the work on behalf of the Ministry, states that 170 separate photographs will be taken. The pictures will overlap, so that each shows an area roughly of ¾ of a mile wide and ½ a mile broad.. The Air Ministry has arranged to place ground signals a mile apart along the route to ensure that the airmen and photographic surveyors keep true to the straight ¾ of a mile belt.

Correspondence.

A CONTRAST RATING FOR PRINTING PAPERS.

To the Editors.

Gentlemen,—There have been three recent suggestions in the "B.J." to the effect that it is desirable for the manufacturers of printing papers to describe the "contrast" of their products batch by batch with a number indicative of the exposure range necessary to record upon any particular paper a white impression at one end of the scale of tones and the deepest black impression possible at the other end. It is considered that such a number would be more precise and informative that the expressions "soft," "vigorous," "portrait," and so on, in present use.

Precise information as to the properties of any particular batch of printing paper would be useful to the photographer in two distinct directions :—

(*a*) To enable him to renew an exhausted stock of paper with the certainty that similar prints would be obtainable on the new stock from the same or similar negatives.

(*b*) To enable him to decide which paper out of his stock of papers would be the most suitable for use with any one particular negative.

Let us consider (*a*) for a moment and examine to what extent a figure denoting the exposure scale of the paper would be sufficient to indicate the character of the resultant print.

In figure 1 there are depicted the characteristic curves of three printing papers which differ in every respect except that they possess the same exposure scale, and would in fact be labelled with

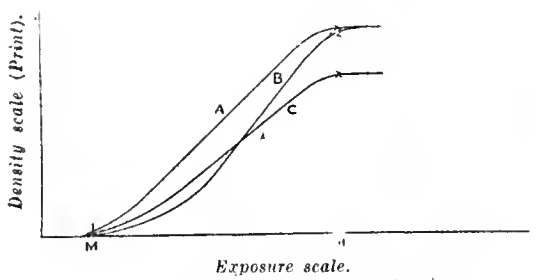

Fig. 1.—Prints A, B and C.

the same "contrast rating number" if manufacturers were to adopt the suggestions of Messrs. Hall, Taylor, and Thermit.

It is certain that these three papers A, B and C would yield prints of a totally different character when printed from the same negative. Paper A is a high-class paper giving a good reading for maximum black, and having a very desirably short under- and over-exposure period, together with a comparatively long straight line portion, indicative of its capacity to translate the negative gradations with fidelity. The gamma of this paper is less than that of paper B and greater than that of paper C. Paper B, possessing the same exposure range, is a paper with a prolonged under-exposure curve and relatively short straight-line portion. Except for the pure white and the deepest black tones, its rendering of the intermediate tones of any one negative would be totally different from the rendering of paper A. Paper C, possessing the same exposure range (MN), differs from A and B in giving a lower reading for maximum black. It would be, perhaps, a paper of different surface characteristics compared with papers A and B, such as a marked matt surface compared with a less matt surface, or its defective black may be due to a faulty emulsion. The rendering on C would be different from that on A or B.

It is certain that the "contrast rating" of a photographic paper cannot be adequately described by a figure indicative of its exposure scale alone. It would be moderately precise if both the exposure scale and the amma infinity were measured and given, or as an alternative the exposure scale and the measure of the maximum black. It would be still more precise if to either of these alternatives were added information as to the relationship between the length of the characteristic curve of the paper which was straight and that portion which was curved, a relationship termed the "rendering power" by Messrs. Mees, Nutting & Jones.

If a photographer were satisfied that a certain paper gave him the prints he required from certain negatives, then it is extremely unlikely that his request to the paper manufacturer for a paper of similar "contrast rating" would bring him a paper capable of giving precisely similar prints.

Let us examine the utility of this "contrast rating measurement" in enabling the photographer to decide what printing paper to use with a given negative. It is desirable in matching a negative with a printing paper to so choose a paper that the density scale (opacity range) of the negative should coincide with, or on occasions be somewhat less than, the exposure scale (range) of the printing paper. Given the exposure scale of the paper by the manufacturer under the title of "contrast rating," the figure which they are now being urged to give, we must in some manner estimate the density scale of the negative. Are we to guess it by viewing the negative in a good light and making an inspection estimate? Personally, I have been inspecting negatives and then actually measuring them for years, and my estimates based upon inspection alone are as erroneous as when I started. A grocer who sold tea and sugar by guesswork without the aid of a pair of scales, and who had practised that procedure for years, would doubtless be confident, unless bankruptcy or police court proceedings supervened, that he was capable of guessing weights with accuracy. It is fairly certain, however, that if he were persuaded to buy a pair of scales he would find that the guessed weight of a commodity was something very different from the real weight. The guessing of a weight with reasonable accuracy is simple compared with the accomplishment of a fairly accurate estimate by inspection of the density scale (opacity range, printing quality) of a negative.

It is quite certain that, in order to make full use of the "contrast rating" figure given by the paper manufacturer the photographer would have to be prepared to measure his negatives. The measurement of negatives involves apparatus which must be designed with care and used with care. Given satisfactory apparatus for the purpose and knowledge of its use it must be remembered that density measurements have two extreme values, a low value reading given when the measurement is made in perfectly diffused light and a high value reading when employing parallel light. The former reading is appropriate for contact printing and enlarging under conditions of perfect light diffusion, and the latter reading is appropriate when enlarging with the aid of a "condenser" lantern, provided that the degree of parallelism of the light illuminating the negative through the condenser is similar to that of the light by the aid of which the negative was measured. In the case of negatives in which the silver deposit is not perfectly neutral in colour, the density reading, no matter how made, will need correction to transform it into a value of use in actual printing.

It seems to me that the utility in practical photography of a figure giving the exposure scale of the paper is fading into insignificance. The figure does not indicate many of the properties of the printing paper emulsion which are vital to the question, and the difficulties in the way of utilising this information, so far as it goes, are sufficiently great to prevent its publication being of real value.

Practical photographers can do a great deal to help themselves in these matters without any additional information from manufacturers as to the numerical constants of the emulsion supplied. Choose a negative which will give a print upon soft Velox paper and will show a touch of white and a touch of black at the two ends of the tone scale. Between these two ends all the remaining negative gradations will be rendered in appropriate shades of grey. Such a negative will have a density scale of about 1.3, equivalent to an opacity range of 1 to 20. Keep that negative for making test prints on any paper. Make such a test print whenever new paper is bought, and if the print so made differs in appearance from any previous print on other papers, or other batches of the same paper, add it to the permanent collection of "differing"—

prints. In the course of a short time there will be formed a small collection of prints showing all the print differences that commercial papers are capable of yielding, inclusive of emulsion differences, paper surface differences, and colour of paper base variations. There will not be many prints in the permanent collection showing marked differences. Paste them on a chart and label them A, B, C, etc., in the order of their contrast. Compare a print from new paper with the prints in the permanent collection and label it accordingly. Store it when labelled in an appropriate compartment, and you have as much information as to its printing properties as you are ever likely to derive from the publication by the manufacturer of the emulsion constants.

The prints on such a chart are merely guides to the category in which new paper should be placed. It is unfair to examine such a chart and say that one print is better than another, unfair to the paper giving the worse print. The prints are purposely made from the *same* negative in order to bring out the paper differences, no matter what characteristic of the paper those differences may be due to. If the test negative chosen be one that gives a normal good print on soft Velox paper, then most of the vigorous gaslight papers will yield harsh prints with missing highlights and buried shadows, and most of the bromide papers will yield flat prints. If, however, such a chart be made, and if, upon the arrival of a new batch of bromide paper, the new paper be found to yield a print from the test negative equally as flat as a print on the chart, then it is certain that the new paper is suitable for all negatives which previously yielded good prints on the "chart" print paper and is equivalent to any stock in hand previously graded as equivalent to the same chart print. I have had the experience of making such a chart and writhing under the comments of brother photographers, to whom the chart conveyed no more than that "vigorous gaslight paper always gives hard prints of no value," and that "Messrs. Blank's bromide paper seemed to yield an unbearably flat result." It did, thus treated; and the fact that it did enabled it to be so classified that there was some chance of finding the right negative to make it yield a normal print of perfect quality.

The finished chart is a guide to the classification of papers in the order of their contrast-giving properties, and nothing else. The finding of a paper to yield a good print from a given negative remains (and is likely to remain, for the reasons already given) a matter of trial and error. The simplest and at the same time the most accurate way of ascertaining the printing capacity of a negative is not to study the negative or attempt to measure it, but to make a print and examine that. The print is either right, or flat, or too contrasted. If the error is flatness, then a paper of greater contrast picked out of the classified stock is the remedy. The classification of the papers has merely shortened the road to success via a trial print on some paper which at a guess the photographer thinks may possibly be about right.

I hope that I am forgiven for the excessive length of this letter. —Yours truly, B. T. J. GLOVER.

FOREIGN PHOTOGRAPHIC LENSES.

To the Editors.

Gentlemen,—In "Nature" of November 3 (page 505) I gave a short account of the result of the examination by the National Physical Laboratory of three lenses, two post-war ones, made in England of English glass, and one pre-war lens made by Goerz. The two English lenses were bought from stock at a large London dealer's, and the Goerz lens was specially selected for me by Messrs. Goerz's London agency.

As most photographic shops are now selling quantities of German lenses, it is to be presumed that the buyers imagine that these lenses are better than English made ones.

The following details may, I hope, help to correct such ideas. The full reports of the National Physical Laboratory being rather lengthy, I give a summary (kindly furnished by the Director of the N.P.L.) of the conclusions arrived at:—

"The series III 2 Doppel-Anastigmat, No. 118,054, by C. P. Goerz, full aperture $f/7$ (f = 176 mm.), has been examined over the field of view corresponding to a half-plate. The lens shows appreciable spherical aberration and distortion, and requires to be stopped down to $f/16$ to give satisfactory definition over the entire plate. The lens fails to reach the standard required for a certificate.

"The series II, Cooke Aviar lens, No. 960,024, by Taylor, Taylor & Hobson, full aperture $f/4.8$ (f = 214 mm.), has been examined over the field of view corresponding to a half-plate. The lens shows a little spherical aberration and slight distortion. The correction for coma, curvature and astigmatism are satisfactory, and at $f/4.8$ satisfactory definition is given over the entire plate. The lens reaches the standard required for a certificate.

"The Cooke telephoto lens, No. 86,732, by Taylor, Taylor & Hobson, full aperture $f/5.8$ (f = 371 mm.), has been examined over the field of view corresponding to a half-plate. As with telephoto lenses in general the distortion is appreciable, and amounts to a displacement of a point at the corner of the plate of nearly 2,3 mm. The corrections for spherical aberration, coma, curvature and astigmatism are satisfactory, and the definition at $f/5.8$ over the entire plate is excellent. The lens reaches the standard required for a certificate."

In another letter, the Director observes that "the Goerz lens is not as satisfactory as either of the Cooke lenses, although, on account of its smaller aperture, a better degree of correction might reasonably be expected."

I think it is a fair statement that the best English photographic lenses more than hold their own with the best Continental ones. Where the Germans score is in the excellence of their publicity departments. Most of our English firms ought to learn how to advertise. —Yours faithfully,

K. C. BROWNING.

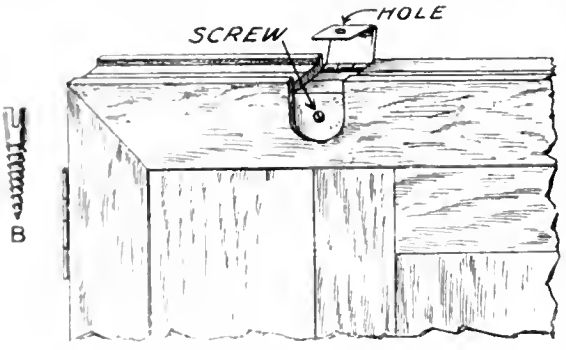
DARK-SLIDE FASTENINGS.

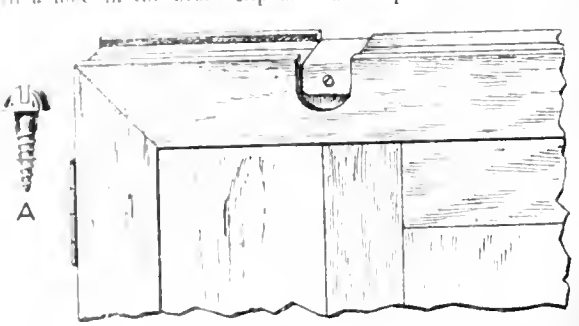
To the Editors.

Gentlemen,—In reference to the paragraph on dark-slides in your issue of November 4, p. 653, I beg to bring to your notice my



method of keeping the brass clips secure. It is the only dodge I know to be reliable.

Drill a hole in the brass clip as near as possible to the centre.



Bore a hole in the wood to correspond with the hole in the brass, screw in fully a small brass screw, remove the screw and cut off the head. Then screw into the wood by means of a pliers, or make

a cut in the top (B) by means of a small (hack) saw. Close the slide and you will find the clip will go into its place with a snap. You can make the grip tight or loose by adjusting the screw, and this is an advantage. If, however, this facility is not wanted a small brass nail (A) may be used, or a small screw with rounded head may be used if one can countersink the brass clip (inside) where it meets the screw head.

An extra safeguard is a rubber band—can be got any size at the stationer's. It must, of course, be slipped off before inserting the slide. When in use it is slipped over the slide to catch each clip.

I have endeavoured to draw the device for further explanation of above description.—Yours, etc.,

Tuam, Co. Galway, T. P. MacNally.
November 8.

THE NODAL SPACE OF A LENS.

To the Editors.

Gentlemen,—In my letter, page 679, of your issue of November 11, there are two errata.

Equation (3) should read $S=D_1-(D_2-D_1)\times\frac{2(u+1)^2}{2u^2-1}$

In the last line, $S=D_1-(D_2-D_1)\frac{18}{0.7}$ and not as written.

The latter error is my mistake, which I regret.—Yours faithfully, R. J. S. Simpson.

Answers to Correspondents.

In accordance with our present practice a relatively small space is allotted in each issue to replies to correspondents.

We will answer by post if stamped and addressed envelope is enclosed for reply: 5-cent International Coupon, from readers abroad.

Queries to be answered in the Friday's "Journal" must reach us not later than Tuesday (posted Monday), and should be addressed to the Editors.

K. J.—The firm we mentioned in our issue of June 3 as supplying a focussing magnifier with a sucker end was Messrs. A. W. Penrose, 347-349, Cathedral Street, Glasgow.

Mrs. F. N.—Legally the assistant was bound to work the full week, that is until the usual closing time on the Saturday, but we think any action for remedy in respect to his earlier leaving would probably be dismissed as trumpery by a magistrate.

W. A. H.—We are sorry we do not know where particulars of M. de Fontenay's work appeared, but are quite sure that you can obtain the information by applying to M. L. P. Clerc, c/o "Revue Francaise de Photographie," 35, Boulevard St. Jacques, Paris.

D. K.—The best suggestion we can make is that the painting should be fenced in on all sides with a kind of tent extemporised from thin muslin erected on a frame, the picture being placed at one end of the tent and the lens pointing into the other open end. This will avoid a good deal of the varnish reflection, but not enough to dispense with the usual panchromatic plate and a deep safelight, say K3.

F. J.—It all depends on what stipulation you made in agreement with the people when arranging the exchange of the cameras on approval. If there was no agreement at all then certainly the usual course is that a person who wishes to inspect an apparatus pays the carriage on it, but if nothing was agreed upon beforehand we do not think that you can hold the people to the payment of the charge on your apparatus.

Basement Dark-room.—Having a large cellar, 21 x 12, with one door leading into a small yard about 4 ft. square, could I convert this cellar into dark-rooms for assistants to work in? If so, would the Factory Inspector pass it? Do dark-room assistants come under the Factory Act?—J. N.

It does not sound a healthy place for assistants to work in, and we think it very likely that the place would not be passed by the Factory Inspector, under whose care assistants employed in workrooms come in accordance with the Factory Act.

S. M.—Under the Registration of Business Names Act you are required to register your business name if it is not your own name. That being so, you are required by the Act to print your name on business stationery, such as note headings or invoices. To omit to do so is a breach of the Act, in respect of which you are liable to be summoned. It is not necessary for you to use your true name in advertisements nor on the photographs which you supply. As regards the business card or price list we think the Act would require that your name should be printed on it. The Act applies equally to people of English nationality and to aliens.

J. O.—(3) For making the negative the best plate is one of the process or photo-mechanical variety, of which almost every maker has his own, or a process panchromatic, such as that of Wratten, if the original you have to copy is in colours. For the lantern-slides the best results will be got on one of the slow lantern plates. (4) There is no book on the production of lantern-slide advertisements, in the making of which there is nothing special beyond what is dealt with in the manuals on lantern-slide making and colouring, *e.g.*, "Practical Lantern Slide Making," by G. T. Harris, 1s. 6d. net, and "How to Colour Photographs and Lantern Slides," by R. Penlake, 1s. 6d. net. Both of these are published by Messrs. Iliffe, 20, Tudor Street, London, E.C.4.

C. J.—(1) We prefer backgrounds to be stretched upon frames and fitted with castors. (2) When so fitted the backgrounds remain quite flat and free from creases. They can be used in any part of the studio, and can be turned to or from the light to make them appear lighter or darker, as may be desired. Backgrounds or rollers must be kept in one position or on a heavy stand which is difficult to move. (3) If the roller system be used it is better to have the roller at the bottom with self-coiling cords to raise and lower it. This method is used for stage scenery and also for lantern screens. The roller tends to keep the background steady and the weight helps to pull out the flutes caused by rolling.

R. A. J.—The light from incandescent mantles is by no means so actinic for gas-light printing as that from a half-watt, but we should think that, say, two high-power mantles would allow sufficiently short exposures on the ordinary gaslight papers from reasonably quick-printing negatives. We do not think that any gaslight would be powerful enough for the slow gaslight papers. The Luna lamp of Messrs. W. C. Hughes is a very good lamp, burning methylated spirit, and being self-contained could be used with one or other printer as required. No doubt there are more powerful incandescent burners for gas, but our experience is that one of the very best is the "Howellite," sold by Messrs. Griffin. Three or four of these inverted burners ought to allow of sufficiently rapid exposures.

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 3212. Vol. LXVIII. FRIDAY, NOVEMBER 25, 1921. Price Fourpence.

Contents.

SUMMARY.

The completion of the two recent articles on scale in optical reproduction takes the form of a somewhat lengthy arrangement of the rules and examples applying to calculations of the size and scale of the image of an object according to the particular circumstances of distance, camera extension, and focal length of lens. It is hoped that in some respects these rules have been made more explicit and free from liability to misuse than has hitherto been the case. (P. 702.)

In a contributed article, Mr. D. Charles describes an enlarging and reducing outfit employing diffused light from a set of half-watt bulbs. (P. 699.)

In his "Paris Notes" M. L. P. Clerc describes further experiments on de-sensitising. Lactic acid is being used for preserving the amidol developer, and a French worker of the Autochrome process employs a supplementary yellow filter during part of the exposure. A new lens and camera just placed on the French market are described. (P. 700.)

In a leading article we outline the measures which can easily be taken for introducing an adequate degree of system into the exposure of plates in the studio. (P. 693.)

The passe-partout style of mounting is capable of being used with good effect for fairly large prints inserted without any surrounding mounts. (P. 693.)

The interest which continues to be taken in automatic enlarging apparatus suggests the opportunity which exists for the combination of an enlarger of this kind with a printing box, providing the facility of the latter for feeding paper and for vignetting and masking. (P. 697.)

A maxim which might be applied with advantage to photographic workrooms, and particularly to those in which plates are tank developed, is that a temperature below that for physical comfort is also unsuitable for the photographic processes. (P. 693.)

It is interesting to look back upon the discussions which took place nearly thirty years ago on the respective merits of plates and film. (P. 693.)

Lieut.-Col. J. T. C. Moore Brabazon appeared before the Royal Commission on Awards to Inventors last week in support of a claim in respect to the invention of aircraft cameras. (P. 710.)

According to the "Scientific American," aerial photographs are being used in the detection of oil fields in Venezuela. (P. 705.)

Messrs. Ilford, Ltd., have declared a dividend of 8 per cent. on the ordinary shares for the year ended October 31. (P. 711.)

At the Royal Photographic Society, on Tuesday evening last, Mr. A. C. Braham gave a successful demonstration of the making of carbon prints by the Carbro process. (P. 709.)

Finders for cameras and an attachment for one-lens stereoscopic photography are the subjects of recent patent specifications (P. 706.)

EX CATHEDRA.

Projection Printing. Notwithstanding the great facilities which are provided by modern enlarging apparatus, it requires to be considered that a profitable field of invention still remains unexplored. As we pointed out in a leading article a month or two ago, the tendency in the future seems likely to be towards making printing (on development papers) an optical projection process. Among studios turning out portraits in quantity at low prices this system has, in fact, been widely adopted for a long time past; and it is somewhat remarkable that manufacturers of printing appliances should not yet have perceived the opportunity which exists for the supply of an apparatus which combines within itself the features of an enlarger and of a rapid printing box or machine. Judging from an illustration, something of this kind has been recently placed on the market in the United States by the Atlantic Photo Supply Co., of Baltimore, for the purpose of providing the means of copying, reducing and enlarging within one apparatus. We think, however, that a less comprehensive apparatus is likely to be more useful, namely, one which will allow of prints being made on scales of enlargement from, say, three times to same size and of upside-down vertical pattern, so that prints may be made with the speed of the present contact printing boxes. A device of this kind should allow of masking and vignetting being readily done, and an apparatus of this type could be designed to provide these facilities without much difficulty.

* * *

Optical Calculations. Although the application of the optical formulæ contained in the article "Scale in Optical Reproduction," which has appeared in our last two issues, is a question of quite simple arithmetic, we realise that there are many people who must have these rules expressed in a form without any mathematical symbols. While that is a perfectly easy thing to do, it cannot be done with the required explicitness in a small space; and therefore our desire to put these formulæ into ordinary language, and to adapt them to the various conditions occurring in practice, must be our excuse for the length of the compilation which appears on other pages of this issue. Even when all is said and done, cases arise in which certain rules or formulæ become misleading. This arises chiefly from the fact that the basic formula for these calculations assumes that a lens has no so-called "depth of focus," that is to say, that for every different distance of the object there is a different and measurable distance of the image from the lens. In consequence of "depth," however, this is not the case, and hence certain formulæ which are commonly included in such collections lead to erroneous results, unless regard is paid to this fact. In the rules which are given in the article on another page we have endeavoured to direct special attention to these cases,

so that the compilation as it stands provides, so we hope, a more explicit guide in these calculations than has hitherto been available. At the same time, the student is advised to make himself familiar with the principles lying underneath the rules, as set forth in the chapters which have appeared in our issues of November 11 and 18.

* * *

Passe-Partouts. The passe-partout method of mounting is often neglected by many professional photographers, though it is one that seems to be particularly well suited for the presentation and preservation of photographic prints, especially in the smaller sizes. The commercial passe-partout frame may be employed, but the shapes, sizes and tints in which these are obtainable are not to every photographer's taste, particularly in the case of those workers whose aim is to produce something distinctive. Some time ago we were looking at a number of pictures framed in this style, and subsequently learned that they were by the Transferotype process transferred to a rough cream drawing paper and bound up in the ordinary way to old cleaned-off 10 x 8 negatives. Though not often done, large prints may be framed "close up," which is a particularly suitable finish for this class of work, especially when a light binding is employed. There are doubtless many photographers who have large negatives stored that are of no further use, and these may be utilised in this way. Many customers, who will not willingly pay the extra cost of framing, may be persuaded to allow the lesser extra charge for passe-partout.

* * *

Film in the 'Nineties. We are reminded of the way in which controversies on matters of photographic practice come up again by noticing the report of a meeting of the now extinct Photographic Club held in June, 1893, and recorded in the "Annual Report" which the Club was accustomed to issue each year. There, nearly thirty years ago, members were debating the modern question of plates *versus* films, as the result of the exhibition of some 15 x 12 negatives taken on Fitch's slow films. The problem of keeping such large films flat for exposure was solved by rubbing the film down on a piece of strawboard covered with Meade's adhesive plaster, a hint that may have its value at the present day. Mr. Mackie, at this meeting, no doubt expressed the general feeling at that time when he declared that the advantages of films were their lightness and ease of storage; there the advantage ceased. Another member put forward the facility of printing from either side, but the rejoinder from the late Mr. Foxlee was characteristic of the *f*/64 school of that day. The plan, he said, might do for large work of the Emersonian kind, but would not answer for fine or small work. The remark shows how far we have travelled in the direction of soft focus, when the suggestion to print through one thickness of celluloid is put aside as inadmissible for "fine work."

* * *

With the Colder Weather Those workers who develop their negatives by the tank method will do well with the advent of the colder days to ensure not only that the developing solution is at the correct temperature when starting development, but also that the temperature is maintained throughout the whole of this operation. A bulk of developing solution may be at its normal temperature, but the fact that it is poured into a cold metal or earthenware developing tank, is enough to cause it to drop ten degrees or more, and it may continue to drop during the whole period, upsetting the time of development calculation completely, unless some means are adopted to prevent this possibility. Some workers add warm water to the stock solution until it is of the correct temperature, but this is worse than useless, as the solution speedily drops again. The only safe way is to keep the apartment in which developing is done, and where the tanks and other apparatus and materials are stored at the right temperature, when the possibility of trouble from under-developed negatives is entirely avoided. Some photographers we know do not make a practice of heating their dark rooms except in the coldest weather, but we would point out that if a room is not warm enough for the needs of modern photographic processes, it is not warm enough for those who work there to give their best attention to the production of good results.

EXPERIMENT AND SYSTEM IN EXPOSURE OF PLATES IN THE STUDIO.

It is fortunate that most plates allow a considerable amount of latitude, within which it is possible to obtain a negative capable of yielding a passable print, for if it were not for this many operators would find themselves faced with a greatly increased proportion of re-sittings. It is not wise, however, to trust too much to this latitude, for doing so not only tends to uneven quality in the prints, but gives endless trouble in printing, even if a selection of various grades of paper is at hand to suit hard and soft negatives.

The growing increase in plate speed renders the making of correctly exposed negatives more difficult than it was when plates which we should now class as of "ordinary" rapidity were used for studio work. The fact is that comparatively few portraitists take any steps to acquaint themselves with the capabilities of the plates they are using. Instead of doing this they either deny themselves the benefits of improvements in emulsion making, by keeping to a plate they are accustomed to, or they flit about from one make to another, in the hope of finding one which suits their particular methods of working. Such people are quite above regarding the makers' formulæ for developers; temperature is ignored, and the difference in time of development necessary for slow and rapid emulsions is overlooked. This may be thought to be an exaggerated statement of the case, but an inspection of the stock of recent negatives in many studios would prove that it is not so. Moreover, a pathetic feature of the matter is, that the operator does not know that his negatives are not as good as they might be in the circumstances.

The portrait photographer has rarely any scientific knowledge or inclination, hence laboratory methods of ascertaining the qualities of a plate are beyond his reach. Still, a ruder method of testing can be carried out and will probably be quite effective for ordinary purposes. It must, however, be recognised as a first principle that the print is the only true test of the quality of the negative, the visual appearance of the negative being an unreliable guide, particularly when the idea exists that the brilliancy of the image is an indication of good quality.

The procedure suggested is to make a series of exposures upon an ordinary sitter under the usual conditions of lighting, the times given ranging between the limits of decided under- and over-exposure. The negatives should be developed at the same time, preferably in one dish, and for the same time, if possible, at a temperature of 60 degs. to 65 degs. Fahr., rather full development being aimed at. Those negatives which show full detail and are not manifestly over-exposed should be preserved and printed by whatever process is used in ordinary

working, care being taken that correct exposure be given if development papers are used. The prints should be dried and mounted so that they can be readily compared with current printed work, since it is difficult to estimate correctly the quality of crumpled or curled scrap prints. If it be felt that further improvement is desirable, a second series of exposures—three or four will be sufficient—should be made, giving the time which is judged to be most nearly correct. These should be developed for different times, so that some may be thinner and some more vigorous than the pattern negative. Prints from these are made on normal paper and without any attempt at dodging the printing. This simple trial which necessitates only the expenditure of a dozen small plates and a few hours of work, will go a long way towards enabling anyone of average intelligence to gain a fair idea of the capabilities of a plate and the treatment necessary to produce negatives of even quality, which will give first-rate prints by any chosen process. At the same time it may be taken that such negatives will give good prints by any process, leaving out papers specially made for abnormally thin or harsh images. The idea that thin images are *necessary* for bromide printing, especially upon the new slower papers, is quite an erroneous one.

In order to compensate for variations in the strength of light, it is useful to employ some form of exposure meter, but it is not necessary to use the instrument in the way prescribed by the makers. The main object is to establish a definite ratio between the time taken for the test paper to tint and the exposure necessary with a certain plate and lens aperture. To obtain this, the time taken for the meter to reach its tint should be noted under normal conditions of light, and this time compared with the exposure which yields a good negative. Thus, supposing the known exposure to be two seconds and the meter time four minutes, we have a ratio of half a second per meter minute. Experiment has proved that variations in exposure, due to the colour of the light, come well within the latitude of the plate, even the change from daylight to half-watt lamps, or from ordinary to isochromatic plates, not seriously affecting the result. It would, however, be advisable to consider the colour of the light to some extent, and to add to or deduct from the exposure as indicated by the meter, according to whether half-watt or enclosed arc lamps were used.

Many errors in exposure are due to non-observance of the *f* value of the diaphragm when the nature of the subject demands the use of a larger or smaller aperture than that generally used. This should not occur when the apertures are marked according to the standard system in which each stop demands double the exposure or the next larger, but in many of the older lenses the stops bear no indication of their values. These should be ascertained, great accuracy being unnecessary, and the result, either as *f* values or as comparative exposures, scratched upon the tang of the diaphragms. It will probably be found that all iris diaphragms are engraved upon one or other of the standard systems.

The effect of the complexion of the sitter and the colour of draperies must be considered in relation to exposure. Though it might be theoretically correct to render a swarthy person in his true depth, it would probably not be agreeable to him or his friends. It is therefore desirable to increase the exposure to such an extent as to give the effect of a normal complexion.

A HALF-WATT ENLARGING AND REDUCING INSTALLATION.

It is probably the case that a half-watt system is not ideal for an enlarging installation as compared with mercury-vapour, but at the time this apparatus was constructed there were several factors that caused a decision in favour of the gas-filled lamps, in addition to the fact that just then it was not possible to obtain the mercury outfits. It was known that a large number of negatives very strongly pyro-stained would be among those to be worked from, and some doubt was felt as to the possibility of satisfactorily enlarging from these by the mercury lights. Then the question of first cost arose, and as it was required to have an installation that would cover a 12 in. by 10 in. negative, a condenser enlarger was ruled out from every point of view. The next consideration was the length of space available in the printing room, and as some rather large work was a probable requirement the outfit was at first built with the camera portion inside the room and the illuminant outside, a window in the partition affording the accommodation for the negatives. A large sheet of iron (painted white, of course) was supported outside this window, as in a daylight enlarger, and above this four half-watt bulbs, each of 1,000 watts, were hung, having a separate switch for each. These switches were fixed inside the room conveniently near the camera. This plan allowed the lights to be switched off between enlargements, and even between trials, thus somewhat compensating for the extra running cost of the light as compared with mercury.

Subsequently certain structural alterations made it essential that the whole of the installation should be inside the darkroom, and this obviously raised several problems, not the least of which was the great heat given out by the large gas-filled bulbs, and the small amount of space which could be spared for the lantern portion of the enlarger. A large box was made, of 1-inch boards, six feet in height and four feet wide, and one foot in depth, and this was left open at the back, whilst the front had an aperture in the centre about 13 in. by 11 in. and the inside was lined throughout with

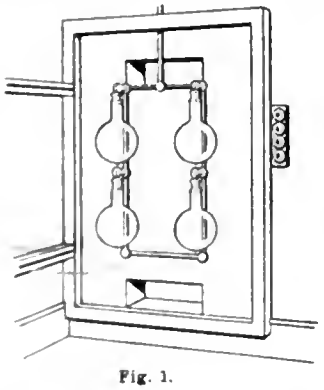


Fig. 1.

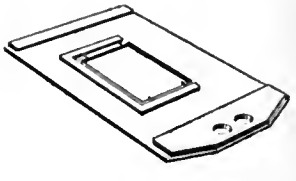

Fig. 2.

asbestos sheet. A frame of 2 in. by 2 in. quartering was built on to the wall to accommodate the open back of the box, and a hole for ventilation was left in the wall near the top as well as near the bottom of the area enclosed within this frame. Reference to figs. 1 and 3 will explain the arrangement.

The camera portion (fig. 3) was made from an old 12 in. by

10 in. camera, with a box about six inches deep at the back end to give a little extra extension. The reversing-back was left on the camera, and the frame holding the focussing screen was altered slightly so that it would slide in and out of the grooves. Similar grooving was fixed between the six-inch box and the "lantern," so that a similar carrier could be inserted there also. As a matter of fact, quite a number of carriers were made of three-ply wood, one for each size of negative from quarter-plate to twelve-by-ten. This is far more convenient than having them "nested," as well as being very much stronger from the wearing point of view and safer for the negatives. The horrible little turnbuttons usually provided on enlarger-carriers, which are so apt to wear loose and let the negatives drop out, were avoided altogether. The slots in the side of the apparatus, through which the carriers slide into the grooves, were made double the width of the grooves,

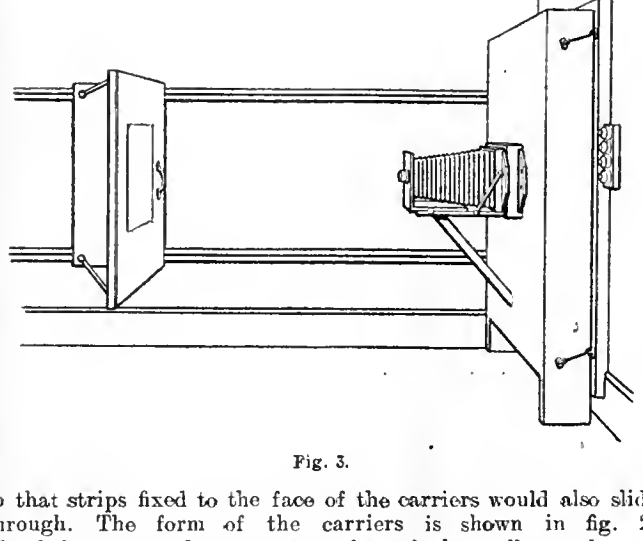

Fig. 3.

so that strips fixed to the face of the carriers would also slide through. The form of the carriers is shown in fig. 2. The hole was made a quarter of an inch smaller each way than the size of the negative to be accommodated, and strips were glued and screwed on three sides to form a rebate, this being made very loose, so that if any detail happened to fall, as occasionally it does, close to an edge of the negative it could be slid over the aperture. Into these strips very thin wire nails were driven and the heads then cut off so that the plates could be slid down from the top and so held securely though without being actually gripped. On removing the carrier from the enlarger and merely turning the top edge downwards the negative slides out and the next is inserted far more rapidly than under the old system.

A sheet of glass is loosely supported just inside the lantern box and helps to keep the heat away from the negatives. The heat may be said to be the only drawback to this installation, and, although the actual light efficiency is probably not so great as in an enlarger on these lines that would be made for smaller negatives only, it is found far better in every way than a condenser outfit that was in use previously. The heat has caused no more trouble in over a year's continuous work than to need a little attention to the joints in the box, and in one case some of the opaque came away from a blocked-out negative that had needed an extra long exposure when making a 20 in. by 30 in. enlargement with the lens stopped down. The heat is never enough to affect the lens in the slightest. Films, if there were many, would be regarded as a nuisance, but what few come along are either bound to a clean glass with lantern-binders, or are dealt with in the condenser outfit before mentioned, which has been retained as a stand-by in case of emergency

The easel is pretty solidly built, and is faced with cork lino of a thick and soft variety, which takes pins easily without leaving a hole when they are drawn out. The board is fastened by strong angle-brackets to runners which slide in the grooved rails, shown in the sketch, which run the full length of the wall. The face of the easel, as well as the entire inside of the lamp-house, are coated with white distemper. This provides a beautifully diffused illumination for retouched negatives without needing any ground-glass, as well as forming a surface on which the image is focussed without needing the continual renewal of white paper, as in most installations. So far the distemper has been applied only once a year. The original four lamps have been in use for quite eighteen months, and still seem to be going strong. That good fortune is attributable partly to the practice of switching off as often as possible, and partly to the fact that two spares are kept safely packed away on a shelf.

It may be added that a spare carrier is kept handy with a waste negative in it that has been fairly covered with lines cut through the film. This affords a rapid and easy means of ensuring sharp focussing, which usually is done rather by sliding the easel than by the pinion of the camera. This method does not alter the size of the image so much and permits of greater freedom of movement. A minor point, but one that adds materially to the convenience of this system, is that the lines on the waste negative are cut with a blunt and not with a sharp knife. This is because a blunt instrument cuts a line with a jagged edge and with occasional bits left across the lines. These irregularities afford a very ready means of knowing if the image on the easel is sharp or not. Most of the negatives that are worked from being complicated mechanical instruments, they are fairly covered with fine detail. Therefore it is not possible to enlarge through an objective of the rapidity that is usually employed when portraits form the majority of the subjects. The type of lens that is favoured for this work is an anastigmat of a maximum aperture of f/8, which seems to give better detail than a more rapid lens stopped down to the same relative opening, and rarely needs stopping down at all. It need hardly be said that for work of this kind the parallelism of the various parts of an installation is far more necessary than in a portrait outfit, which does not call for extreme sharpness all over.

At the same time, this installation avoids that deadly sort of sharpness that records every flaw in the glass and every ridge of any retouching medium that one may have to employ, and renders the retouching itself as so much wire-netting. It reproduces the quality of a negative without making the grain noticeable, even in large sizes, and the results rarely receive more than a few minutes' spotting, even when required for decorating the walls of board-rooms and the like.

D. Charles.

PARIS NOTES.

Before writing of photographic matters which have attracted notice in France since the last instalment of these notes, I should like to express my thanks to the many people who I had the pleasure of meeting in London during a fortnight which passed all too quickly. Their cordial reception was a great pleasure to me and no less so the many interesting exchanges of views which I was permitted to share.

Desensitizers.

At the October meeting of the Scientific Section of the French Photographic Society, M. J. Desalme made a preliminary announcement of the desensitising properties of the alkaline salts of picramic acid, which, for want of time, he had tested on bromide papers. Picramate of soda, when used as a desensitiser of plates, requires to be employed in much

stronger solution than safranine, but, on the other hand, has the advantage of being much more readily washed out from the gelatine film or the skin. Samples distributed by M. Desalme among his fellow-members will allow the latter to test the product for themselves. At the time of writing, these experiments are not complete, and have been made only on ordinary (non-ortho) plates or those sensitive to green, but they show that a 1 per cent. solution of picramate of soda has a desensitising action slightly inferior to that of a 1:2,000 solution of safranine.

Recently a saturated solution of aurantia in acetone was placed on the market as a desensitiser, and has been the cause of skin affections, and even, in certain cases, of more serious poisoning. The harm results from the full exposure of the skin to the toxic action of the aurantia in consequence of the complete removal of natural grease. The aurantia desensitiser is now supplied in the form of a much less concentrated solution in alcohol. Nevertheless, it is recommended to observe care in avoiding contact of the skin with the solution, as sold. In case the solution is spilt on the fingers, the latter should be well rinsed with spirit. In the diluted state in which it is used for bathing plates, the aurantia solution is altogether harmless.

Preserving the Amidol Developer.

M. L. J. Bunel has recently drawn attention to the value of the additon to the amidol developer of commercial lactic acid (sp. gr., 1.21) in the proportion of 5 c.c.s. per litre (1 drachm to 25 ozs.). The chemical properties of lactic acid are closely allied to those of glycollic acid, recently recommended in the "B.J." (1921, March 4, p. 125) for the same purpose. Also lactic acid is more readily obtained and is equally effective, its preserving action being greatly superior to those of metol, advised not long ago by Signor R. Namias. M. Lobel has compared a developer preserved with lactic acid with one containing stannous tartrate, according to Desalme ("Paris Notes," June 17, 1921, p. 359) and also with one not containing a special preservative and with the usual MQ formula. An equal volume of each of these four developers were left freely exposed to the air in identical vessels. A band of bromide paper exposed under a sensitometric step-wedge was developed each day in each bath. M. Lobel thus found that the amidol developer without special preservative continued to develop only until the fourth day, but when preserved with either stannous tartrate or lactic acid maintained its developing powers unimpaired up to the eighth day. The MQ solution continued to develop up to the tenth day.

It is important to note that in normal conditions a developer which is kept in a corked bottle, even if only partly filled, retains its activity much longer. An amidol developer becomes strongly coloured long before its developing power is exhausted. In the case of used developer, this change is still more marked, owing to the formation of colloid silver, and M. Lobel some time ago drew attention to a simple means of precipitating the colloid silver and thus prolonging the life of the developer. For this purpose addition is made of 200 gms. sodium sulphate to each litre of bath (1 oz. per 5 fluid ozs.).

The Autochrome Process.

Although many skilled users of the Autochrome plate do not admit any variation in its quality, others frequently experience a tendency to a slight predominant blue tint. It appears that those expressing themselves fully satisfied with the uniformity of the product at the present time are chiefly those who adhere to the pyro-ammonia developer recommended by M.M. Lumière on the introduction of the plates. Hence it seems that the tendency to blueness is counterbalanced by the colour of the pyro image. Such tint, when it is not too pronounced, is counter-balanced by toning the image to a brownish colour, for example, by uranium, or by binding up the transparency with a gelatine-coated glass slightly tinted in the complementary colour, but it is better in every respect to obtain a perfect result without the use of these methods.

At a recent meeting of the Colour Section of the French Photographic Society, M. Schitz, secretary of the Stereo Club, showed a very fine collection of landscape Autochromes made during the summer. M. Schitz is one of the most active of our colour workers and has adopted his own methods of dealing with Autochrome plates which exhibit a tendency to blueness. Preliminary tests showed him that with a lens aperture of *f*/7.5, the best time of exposure is exactly equal to the time required for the paper of the Imperial exposure-meter to darken to the standard tint, with the precaution that the paper is exposed to the light coming from the subject, excluding direct light from the sky. He puts his exposure-meter upright on the camera facing the subject, covering it by a piece of paper or card. He uncovers it when opening the lens and closes the latter as soon as the paper has darkened to the tint. During about a quarter of the exposure he holds against the lens a Wratten K1 filter film, in supplement to the action of the customary Lumière filter. The first development is done (after desensitising) with amidol containing little bromide.

At the same meeting Dr. A. Polack, an opthalmist of repute, showed some impressionistic studies obtained with an anachromatic lens, the chromatic aberration of which was purposely exaggerated. The results were put forward as experimental, so I refrain for the present from commenting on them.

Some New Introductions.

The Société d'Optique et de Mécanique de Précision (S.O.M.) has just introduced a new *f*/4.5 anastigmat named the Flor, the front component of which consists of two glasses with an air space between them, whilst the rear component is formed by three cemented glasses. The corrections have been carried out to a very high degree, particularly as regards coma, and the lens has a remarkably flat field. The lens of 135 mm. focal length (= 5 5-16 inches) is designed for a 9 × 12 cm. plate, yielding a sharpness of definition of 0.1 mm. (1-250th inch) over a field of about 6¼ inches diameter, which is a quarter of an inch greater than the diagonal of the plate. A sharpness of definition of 0.05 mm. (1-500 inch) is obtained over a field of 4¾ inches diameter. Owing to the favourable distribution of the corrections, the depth of field is distinctly greater than that which is customarily found in a lens of the same relative aperture and focal length.

An ingenious camera of very small size has recently been made by Messrs. Krauss, although it cannot be said that the makers have been very happily inspired in the form which they have given to it, namely, that of a small automatic pistol. Nor in the name, which is the "Photo-Revolver." I should be inclined to fear retaliation by some passer-by whose photograph I might have obtained with the camera. However, the little apparatus is fitted with an *f*/4.5 Krauss "Tessar" in focussing mount, and carries 48 plates of 22 × 36 mm. size, equivalent to about ⅞ × 1⅜ inches. These plates are obtained by cutting into six those supplied for the Verascope and similar stereoscopic cameras. The four-speed ever-set shutter is controlled indirectly by a trigger. On pushing the trigger the lens front is moved to the rear; this front is fitted with four rods (very accurately calibrated), which are caused to bear on the emulsion surface of the plate (not on the metal sheath which holds the plate). It is only after this contact has been made, with consequent assurance that the plate is in the position of the sharp image, that the shutter is released. Springs fixed round each of the rods bring the lens front back to its normal position as soon as the picture has been taken and when the trigger has been let go. The changing box, which forms the handle of the revolver, is made in two adjacent divisions, each operated by a blind which conveys a plate from one division to the other and *vice versâ*.

L. P. Clerc.

SCALE IN OPTICAL REPRODUCTION.

PART II.

THE relations between the respective distances of object and image from the lens and the scale of reproduction having been set forth in the previous chapter, and the departures therefrom owing to depth of focus having been considered, we can now proceed to express these relations in the various forms appropriate to the different calculations which occur in practice. We must first define the meanings attached to the various symbols.

Explanation of Terms in Formulæ.

Object is the thing reproduced by the lens, viz., a painting or any other object in ordinary photography, or a negative in enlarging; or a lantern-slide or section of cinematograph film in projection.

Image is the reproduction (smaller, same size, or larger) formed by the lens, viz., on the ground glass of a camera, on the enlarging easel, or on the lantern screen.

f is the *focal length* of the lens, or "focus" as often termed.

u is the *distance of the object* from the lens, strictly from the node of admission, which in a symmetrical doublet lens may be assumed to be near to the diaphragm. In enlarging, it is the distance of the negative from this point in the lens; in projection, it is the distance of the lantern-slide or film from this point in the lens.

v is the *distance of the image* from the lens (corresponding with an object distance of u), strictly from its node of emergence, which also in a symmetrical doublet lens may be assumed to be near to the diaphragm. In referring to conditions in ordinary photography v is spoken of as the "camera extension." It is the distance from lens to easel in enlarging, and from lens to screen in lantern projection.

D is the *distance from object to image*, neglecting the nodal space which almost always is negligibly small compared with D.

R is ratio of linear size of image to linear size of object, that is, the number of times that the size of the object divides into that of the image. Hence, when reproducing on an enlarged scale R is greater than 1: it is the *number of times of enlargement*. In the formulæ which follow, those employing R are indicated in connection with enlargement calculations for the purpose of avoiding fractions.

When reproducing same size, $R=1$.

When reproducing on a reduced scale, R is a fraction. Calculations relating to reduction are therefore more conveniently made by using r instead of R.

r is the ratio of the linear size of object to the linear size of image, that is, the number of times that the size of the image divides into that of the object. Hence, when reproducing on a reduced scale, r is greater than 1: it is the *number of times of reduction* or "*reduction figure.*" For this reason formulæ employing r are indicated in connection with calculations relating to reduction.

When reproducing same size, $r=1$.

When reproducing on an enlarged scale, r is a fraction. While it is common to speak of reproduction on a reduced scale in terms of R or r (e.g., "reducing to 1-10th" or "reducing 10 times"), the process of enlarging is described in ordinary language only in terms of R, i.e., enlarging so many times.

E_u is the *extra-focal distance of the object*, that is, the distance of the object from the front focus of the lens (for parallel rays). It is the distance of the object less 1 focal length of the lens, that is, is equal to $u-f$.

E_v is the *extra-focal distance of the image*, that is the distance of the image from the rear focus of the lens (for parallel rays). It is the distance of the image less 1 focal length of the lens, that is, is equal to $v-f$.

As far as possible the appropriate purpose of each formula is indicated by its heading. Explanatory notes also indicate the cases in which depth of focus causes certain formulæ to be inapplicable under certain conditions. Particularly in respect to Formulæ Nos. 3, 6, 11 and 12 (in case of large scale of reduction), and to Nos. 2, 5 and 9 (in case of lantern projection), the effect of small image distance or object distance relatively to the focal length requires to be understood from the considerations set forth in the preceding chapter.

In using the formulæ, all measures of length must be in the same units—feet or inches

Size of image from size of object, camera extension and distance of object.

$$\text{image} = \text{object} \times \frac{v}{u} \quad . \quad . \quad (1)$$

The size (linear) of the image of an object in sharp focus *with any lens* is equal to the size of the corresponding dimension of the object multiplied by the camera extension v and divided by the distance u of the object.

EXAMPLE.—In photographing a house 40 ft. × 20 ft. 60 yds. distant, camera extension is 6 inches. What is the size of the image of the house? 40 ft. = 480 ins. 60 yds. = 2,160 ins. $480 \times 6 \div 2{,}160 = 1\frac{2}{3}$ ins. The image of the house therefore measures $1\frac{2}{3} \times 5/6$ in.

Size of image from size of object, focal length of lens, and distance of object.

$$\text{image} = \text{object} \times \frac{f}{u-f}, \text{ i.e., object} \times \frac{f}{E_u} \quad . \quad (2)$$

The size (linear) of the image of an object at a distance u in sharp focus with a lens of focal length f is equal to the size of the corresponding dimension of the object multiplied by the focal-length of the lens, and divided by the distance of the object less one focal length.

EXAMPLE.—A picture 12 × 6 ft. 20 ft from the lens is photographed with a 10 inch lens. What is the size of the copy? 12 ft. = 144 ins. 20 ft. = 240 ins. $144 \times 10 \div (240 - 10) = 144 \times 10 \div 230 = 6.26$ ins. The copy therefore measures 6.26×3.13 ins.

Note (*a*).—If the object is at such a great distance that f is a negligible proportion of u, this formula becomes

$$\text{image} = \text{object} \times \frac{f}{u};$$

that is, the size of the image is equal to the size (linear) of the object multiplied by the focal length and divided by the distance.

In like circumstances, the size of the object is equal to the size of the image multiplied by the distance and divided by the focal length.

Example.—What is the size of the image of the full moon obtained with a 10 inch lens? Object measures, say, 2,000 miles: distance is, say, 240,000 miles. Therefore image is $2{,}000 \div 240{,}000 \times 10 = 1/12$ inch.

On the other hand, if the object distance is very little greater than the focal length of the lens, as in lantern and cinematograph projection, calculations based on this formula and on Nos. 5 and 9 cease to be precise owing to depth, and still more to inability to measure the distance u with sufficient accuracy.

Note (*b*).—It will also be understood that when the object distance u is very great relatively to the focal length, the image distance v becomes nearly equal to f, and in consequence of depth focus actually equal to f. For this reason in these conditions

formulæ involving $v-f$ cease to apply, viz., Nos. 3, 6, 11 and 12, and Nos. 2, 5, 9 and 13 should be used.

Size of image from size of object, camera extension and focal length of lens.

$$\text{image} = \text{object} \times \frac{v-f}{f}, \text{ i.e., object} \times \frac{Ev}{f} \quad . \quad (3)$$

The size (linear) of the image of an object obtained in sharp focus with camera extension v and lens of focal length f is equal to the size of the corresponding dimension of the object multiplied by the camera extension (less one focal length) and divided by the focal length.

EXAMPLE.—A postage stamp measuring 1 × ¾ in. is copied with 2-in. lens and 8-in. camera extension. What are dimensions of copy? 1 × (8 − 2) ÷ 2 = 3 ins. Enlargement of stamp measures 3 × 2¼ inches.

Note.—At very great distances of the object, or with a small stop, such that the image is in focus at a distance f behind the lens (*i.e.*, $v = f$), this formula ceases to apply. See Note (*b*) to Formula 2.

Size of object from size of image, distance of object and camera extension.

$$\text{object} = \text{image} \times \frac{u}{v} \quad . \quad . \quad . \quad (4)$$

The size (linear) of an object in sharp focus *with any lens* is equal to the size of the corresponding dimension of the image multiplied by the distance u of the object from the lens and divided by the distance v of the image from the lens.

EXAMPLE.—In photographing a tablet 6 ft. distant, camera extension is 8 and image is 2 × 3 inches. Object dimension of 2 inch dimension of image is 2 × 72 ÷ 8 = 18. Object is therefore 18 × 27 inches.

Size of object from size of image, distance of object and focal length of lens.

$$\text{object} = \text{image} \times \frac{u-f}{f}, \text{ i.e., image} \times \frac{Eu}{f} \quad (5)$$

The size (linear of an object at a distance u in sharp focus with a lens of focal length, f is equal to the size of the corresponding dimension of the image multiplied by the distance of the object less one focal length and divided by the focal length.

EXAMPLE.—The image of a flagstaff 160 ft. distant photographed with a 12-inch lens measures 5 inches. 160 ft. = 1,920 ins. Object measures 5 × (1920 − 12) ÷ 12 = 5 × 1908 ÷ 12 = 795 ins. = 66 ft. 3 ins.

See also *Note* (*a*) to Formula 2.

Size of object from size of image, focal length of lens and camera extension.

$$\text{object} = \text{image} \times \frac{f}{v-f}, \text{ i.e., image} \times \frac{f}{Ev} \quad . \quad (6)$$

The size (linear) of an object photographed with lens of focal length f and camera extension v is equal to the size of the corresponding dimension of the image multiplied by the focal length and divided by the camera extension less one focal length.

EXAMPLE.—When copying-enlarging a shell with a 2-inch lens the image measures 8 inches with 18 inches camera extension. The size of object is 8 × 2 ÷ (18−2) = 8 × 2 ÷ 16 = 1 inch.

Note.—At very great distances of the object or with a small stop such that the image is in focus at a distance f behind the lens (i.e., $v = f$), this formula ceases to apply. See *Note* (*b*) to Formula 2.

Scale of reproduction (*R* or *r*) from distance of object, distance of image and focal length of lens.

$$R = \frac{\text{size of image}}{\text{size of object}} \text{ (linear).}$$

$$r = \frac{\text{size of object}}{\text{size of image}} \text{ (linear).}$$

Degree of reduction or enlargement with given camera extension and distance of object.

$$R = \frac{v}{u} \quad . \quad . \quad . \quad . \quad . \quad (7)$$

The scale of reproduction (proportion of image to object) is equal to the camera extension divided by the distance of the object.

EXAMPLES.—A painting 8 ft. from the lens is obtained in sharp focus with 32-ins. camera extension (this would be with a 24-inch lens), 8 ft. = 96 ins. 32 ÷ 96 = ⅓, that is, the scale of reproduction is reduction to one third.

A midget photograph 3½ ins. from lens is copy-enlarged so that the camera extension is 21 ins. 21 − 3½ = 6, that is, the scale of reproduction is 6-times enlargement.

Note.—If the object is at a very great distance, say 100 or 1,000 times the focal length, the camera extension, is practically equal to the focal length, that is to say, f may be used in place of v in above formulæ.

Degree of reduction with given distance of object and camera extension.

$$r = \frac{u}{v} \quad . \quad . \quad . \quad . \quad . \quad (8)$$

The scale of reproduction (proportion of object to image) is equal to the distance of the object divided by the camera extension.

EXAMPLES.—A painting 8 ft. from the lens is obtained in sharp focus with 32 ins. camera extension (this would be with a 24-in. lens), 8 ft. = 96 ins. 96 ÷ 32 = 3, that is, the degree of reduction is three times. (Reduction figure = 3.)

The second comparative example cannot very well be cited by way of exhibiting the relation of *R* and *r*. While we speak of reduction "to one-fourth," or "four times," meaning thereby the same thing, we do not speak of the process of enlargement in corresponding terms.

Note.—If the object is at a very great distance, say 100 or 1,000 times the focal length, the camera extension is practically equal to the focal length, that is to say, f may be used in place of v in above formula.

Times of enlargement with given distance of object and focal length.

$$R = \frac{f}{u-f} \quad \frac{f}{Eu} \quad . \quad . \quad . \quad (9)$$

The scale of reproduction (times of enlargement) is equal to the focal length of the lens divided by the distance of the object (less one focal length).

EXAMPLE.—In a projection lantern, a 10-inch projection lens cannot be brought nearer to the slide than 10½ inches. What is maximum magnification? 10½ − 10 = ½. Magnification is 10 ÷ ½ = 20.

See *Note* (*a*) to Formula 2.

Degree of reduction with given distance of object and focal length.

$$r = \frac{u-f}{f} = \frac{Eu}{f} \quad . \quad . \quad . \quad (10)$$

The scale of reproduction (reduction figure) is equal to the distance of the object (less one focal length) divided by the focal length.

EXAMPLE.—A painting has to be photographed at a distance of 15 ft. with a 12-inch lens. What is the degree of reduction? Expressing the data in ft., 15 − 1 = 14. 14 ÷ 1 = 14, i.e., reduction is to 1 14th.

Times of enlargement (maximum) with given camera extension and focal length.

$$R = \frac{v-f}{f} = \frac{Ev}{f} \quad . \quad . \quad . \quad (11)$$

The scale of reproduction (proportion of image to object) is equal to the camera extension (less focal length of the lens) divided by the focal length.

EXAMPLES.—Camera has extension of 14 inches. What is greatest degree of enlargement that can be obtained when using 4-inch lens? 14 − 4 = 10 inches. 10 ÷ 4 = 2½: that is, maximum enlargement is 2½ times.

A hall allows 30 ft. between lens and screen. What is maximum size of picture from 3 × 3 lantern slide with 6-inch projection lens? 30 ft. = 360 ins. 360 − 6 = 354. Magnification is 354 ÷ 6 = 59 times. Therefore 3-inch slide is 14¾ ft. on screen.

Reduction figure with given camera extension and focal length.

$$r = \frac{f}{v-f} = \frac{f}{Ev} \quad . \quad . \quad . \quad (12)$$

The scale of reproduction (proportion of object to image) is equal to the focal length of lens divided by the camera extension less one focal length.

EXAMPLE.—In photographing with 6-in. lens, camera extension is 8 inches. 8 − 6 = 2. 6 ÷ 2 = 3; that is, reduction figure is 3

Note.—At very great distances of the object relatively to the focal length or when a small stop is used such that the image is in focus at a distance f behind the lens (*i.e.*, $v = f$) this formula ceases to apply. See *Note* (*b*) to Formula 2.

Calculation of distance of original, camera extension, focal length of lens and working space in photographing on various scales of enlargement or reduction.

For enlargement calculations, since, in these latter, R *is greater than* 1, *and is the number of times of enlargement.*

Distance of object for enlarging R *times with a given focal length of lens.*

$$u = \frac{f}{R} + f \quad . \quad . \quad . \quad . \quad (13)$$

$$Eu = \frac{f}{R} \quad . \quad . \quad . \quad . \quad (13a)$$

To find distance of original or negative from lens for given degree of enlargement, divide focal length of lens by required number of times of enlargement and add one focal length.

EXAMPLE.—For 6-times enlargement of negative with 3-inch lens. 3 ÷ 6 = ½ inch. Therefore required distance of negative from lens is ½ + 3 = 3½ inches.

Camera extension (or distance between lens and easel) for enlarging R *times with lens of given focal length.*

$$v = f\,R + f \quad . \quad . \quad . \quad (15)$$

$$Ev = f \times R \quad . \quad . \quad . \quad (15a)$$

To find camera extension or lens-easel distance for given number of times of enlargement, multiply focal length of lens by degree of enlargement and add 1 focal length.

EXAMPLE.—Enlarging 4¼ × 3¼-in. plate to 8½ × 6½ ins. with 12-inch lens = 2—times enlargement. 12 × 2 = 24. 24 + 12 = 36 ins. = 3 ft.

Focal length for copying-enlarging or projecting R *times with object at a given distance.*

$$f = u \times \frac{R}{R+1} \quad . \quad . \quad . \quad (17)$$

Multiply the distance by the number of times of enlargement and divide by a number 1 greater than the number of times of enlargement.

EXAMPLE.—For enlarging a negative 5 times in an enlarging box providing 8 ins. from negative to lens, what focal length is required? 8 × 5 ÷ 6 = 6⅔ inches. The lens requires to be fixed so that its node of admission is 8 inches from negative.

Maximum focal length permitted by given camera extension or lens-easel distance when enlarging R *times.*

$$f = \frac{v}{R+1} \quad . \quad . \quad . \quad . \quad (19)$$

Add 1 to the number of times of enlargement and divide into the available camera extension.

EXAMPLE.—In a camera for copying-enlarging up to 4 times, an extension of 30 inches (lens to plate) can be obtained. What is the maximum focal length of lens which can be used? 4 + 1 = 5. 30 ÷ 5 = 6. Maximum focal length is 6 inches.

For reduction calculations, since, in these latter, r *is greater than* 1, *and is the "reduction figure."*

Distance of object for reducing r *times with a given focal length of lens.*

$$u = (r+1) \times f \quad . \quad . \quad . \quad (14)$$

$$Eu = r \times f \quad . \quad . \quad . \quad (14a)$$

To find distance of object from lens for given number of times of reduction, add one to reduction figure and multiply by focal length.

EXAMPLE.—In photograph taken with an 8-inch lens, the figure of a tall man appears as 2 inches. What was the distance of the man from the camera? A 2-inch image of 6-ft. man is a reduction of 1/36th. $r + 1 = 37$. 37 × 8 = 296 ins. = 26 ft. 2 ins.

Camera extension for reducing r *times with a given focal length of lens.*

$$v = \frac{f}{r} + f \quad . \quad . \quad . \quad (16)$$

$$Ev = \frac{f}{r} \quad . \quad . \quad . \quad . \quad (16a)$$

To find camera extension when reducing, divide focal length of lens by reduction figure and add 1 focal length.

EXAMPLE.—Copying 8½ × 6½ ins. to 4¼ × 3¼ ins. with 12-inch lens. Reduction figure = 2. 12 ÷ 2 = 6. 6 + 12 = 18 ins.

Maximum focal length for reducing r *times with object at a given distance.*

$$f = \frac{u}{r+1} \quad . \quad . \quad . \quad . \quad (18)$$

Add 1 to the reduction figure, and divide into the distance of the object.

EXAMPLE.—In making the copy of a painting on a scale of one seventh, what focal length is required if the painting is 20 ft. distance? u = 20 ft. r = 7. $r + 1$ = 8. The required focal length is, therefore, 20 ÷ 8 = 2½ ft. = 30 ins.

Maximum focal length permitted by given camera extension when copying an original on a scale of r *times reduction.*

$$f = v \times \frac{r}{r+1} \quad . \quad . \quad . \quad (20)$$

Multiply camera extension by reduction figure, and divide by a number 1 greater than reduction figure.

EXAMPLE.—In copying originals half scale with camera of 9 inches extension, what is maximum focal length of lens which can be used? 9 × 2 = 18. 18 ÷ 3 = 6 ins. Focal length must not be greater than 6 ins.

Maximum focal length permissible when enlarging R *times or reducing* r *times within a given distance from object to image.*

$$f = \frac{D \times R}{(R+1)^2} = \frac{D \times r}{(r+1)^2} \quad . \quad . \quad (21)$$

Add 1 to the reqoired number of times of enlargement or reduction, and multiply the resulting number by itself. Divide the resulting number into the available object-image distance multiplied by the number of times of enlargement or reduction.

Examples.—In a room measuring 12 ft. enlargements up to 9 diameters have to be made. What is the greatest focal length of lens which can be used? Allowing 3 ft. for spaces behind negative and enlarging easel. D = 9 ft. = 108 ins. R + 1 = 10. 10 × 10 = 100. 108 × 9 = 972. 972 ÷ 100 = 9.72 = 9¾ inches approximately.

In a studio of 24 ft. run, what is the greatest focal length which can be used for a full-length portrait on a 6 × 4-in. plate? Taking height of sitter at 70 inches and image on plate as 5 ins., r = 14. Allowing 3 ft. for spaces behind sitter and camera. D = 21 ft. 21 × 14 = 294. 14 + 1 = 15. 15 × 15 = 225. 294 ÷ 225 = 1.307 ft. = 15.68 ins. = 15¾ ins. nearly.

Minimum distance required between object and image when enlarging R *times, or reducing* r *times with lens of given focal length.*

$$D = \frac{(R+1)^2 \times f}{R} = \frac{(r+1)^2 \times f}{r} \quad . \quad (23)$$

Add 1 to the number of times of enlargement or reduction, multiply the resulting number by itself, and then by the focal length. Then divide by the number of times of enlargement or reduction.

Examples.—Enlargements up to 10 diameters are to be made with 8-inch lens. What space is required between negative and easel? R + 1 = 11. 11 × 11 = 121. 121 × 8 = 968. 968 ÷ 10 = 96.8 ins. = 8ft. ¾ in.

For making full-length cabinet portraits with 12-inch lens, what distance is required between sitter and focussing screen? If sitter is 70 inches and figure 5 inches on negative, r = 14. r + 1 = 15. 15 × 15 = 225 ins. 225 × 12 = 2,700. 2,700 ÷ 14 = 192¾ = 16 ft. ¾ in.

For most purposes it is sufficient to use the approximate formula :—

$$D = (R+2) \times f = (r+2) \times f \quad . \quad . \quad (24)$$

Add 2 to the number of times of enlargement or reduction, and multiply by the focal length

Maximum focal length permissible when enlarging R *times, or reducing* r *times within a given distance of object to image.*

Approximate Formula.

By neglecting the distance between the image and the rear focus when reducing, or between the object and the front focus when enlarging or projecting, Formula No. 21 may be given the much simpler form of No. 22. This approximate formula is quite exact enough for most enlarging and studio calculations, provided the number of times of reduction or enlargement is greater than about 6. If this is the case the distance which is left out of account is less than one sixth of the focal length of the lens.

$$f = \frac{D}{R+2} = \frac{D}{r+2} \quad . \quad . \quad . \quad (22)$$

Add 2 to the number of times of enlargement or reduction, and divide into the distance available between object and ground glass (or enlarging easel or projection screen).

Examples (data as for Formula 21).—D = 108. R + 2 = 11. 103 ÷ 11 = 9.82 ins.

D = 21 ft. R + 2 = 16 21 ÷ 16 = 1.312 ft. = 15.744 ins = 15¾ ins.

Degree of enlargement or reduction permissible within a given separation of object and image and with given focal length of lens.

This is the only calculation in scale of reproduction which cannot be worked out exactly by ordinary arithmetic. For precise calculation it is necessary to solve the quadratic equation.

$$2R^2 - (D - 2f)\ R + 2 = 0.$$

The easiest way is to guess the enlargement or reduction figure, and test the guess by using the guessed value of R or r in Formula No. 23

Example.—If a space of 5 ft. is available for distance between negative and easel, what is greatest degree of enlargement that can be done with 10 in. lens? Guessing 4, D = 5 × 5 × 10 ÷ 4 = 62½ ins. = 5 ft. 2½ ins. The permissible number of times of enlargement is, therefore, very nearly 4.

Another method is to use the approximate formula

$$R \text{ (or r)} = \frac{D-2f}{f} \quad . \quad . \quad . \quad (25)$$

Subtract twice the focal length from the permissible distance between image and object, and divide by the focal length. This formula is near enough for most purposes if the enlargement or reduction figure is greater than 6.

Example (data as above) : 60 − 20 = 40. 40 ÷ 10 = 4.

G. E. B.

More Camera Smuggling.—More smuggling fines, to the value of over £650, were imposed at Dover on Saturday last. Jamura Sudo, giving an address at an hotel in London, was fined £87 for illegally importing binoculars, cameras, opera glasses, and carriage clocks when landing at Dover, and Louis Paul Hanosseur was fined £560 4s.

Selective Focussing in Cinema Work.—An example of the rapid progress in French film methods is afforded by a new picture, "Sibilla, the Dancer," shown privately in London last week. It was produced, the "Evening News" tells us, by Marcel L'Herbier, and contained so many novel ideas in screen interpretation of a story that the firm which is handling it in England thought it wisest to cut most of them out. The producer calls his film a "psychological picture," and by "picture" he means the photographic image. He says he is trying to achieve "an enlargement of the vocabulary of the cinematographic expression by the use of partial blurs, total blurs, and distorted vision." Thus in the film a scene which has been retained shows the dancer out of focus as she sits among other dancers in the cafe, who are perfectly clear. She is not present herself, because her mind is elsewhere, and when someone recalls her to the present she comes into sharp definition. Similarly, as her mind wanders again when she is dancing, the assembly in front of her is out of focus, to show that she only half realises that it is there.

Secret Told by the Camera.—Remarkable evidence was given at Wood Green last Saturday when Ralph Hammond and Percy Edk. Wood were charged on remand with breaking into houses and stealing property. A detective said that in a box belonging to Hammond he found some photographs of Hammond sitting in a room at Wood's house. The police had since taken photographs of the apartment, revealing identical "scenery." The room contained extensive plant for melting down and separating metal, and witness produced a muffle furnace which figured in the photographs. Attached to the furnace was an oxygen cylinder and rubber gas-piping, and the furnace was still quite hot when witness called. Both men were committed for trial.

Aeroplane Photographs of Oil Fields.—The "Scientific American" states that a British oil company is using two "flying boats" to survey the delta of the Orinoco River in Venezuela. It appears that oil-bearing lands in this part of the world are distinguished by the partial destruction of the vegetation, and it is believed that an aerial photographic survey of the region will afford a rapid method of both locating oil fields and of discovering the most suitable forest paths and waterways for an approach to the fields. An opening is cut in the boat bottom to allow the camera lens a view, and this hole is fitted with a water-tight manhole cover secured by a kind of breech-block action. The camera can be raised or lowered into position.

FORTHCOMING EXHIBITIONS.

November 23 to 26.—Rotherham Photographic Society. Particulars and entry forms from the Hon. Exhibition Secretary, Sydney G. Liversidge, "Orissa," Gerard Road, Rotherham.

December 3 to 17.—Scottish Photographic Circle. Hon. Secretary, W. S. Crocket, 10, Parkgrove Terrace, Tolleross, Glasgow.

1922.

January 21 to February 4. Partick Camera Club. Latest date for entries, January 30. Particulars from the Hon. Secretary, James Whyte, 51a, Peel Street, Partick, Glasgow.

February 11 to 25.—Scottish Photographic Salon. Particulars from the Secretary, James F. Smellie, Braefindon, Allanshaw Street, Hamilton.

February 14 to 17.—Exeter Camera Club. Particulars from C. Beauchamp Hall, Hon. Exhibition Secretary, Exeter Camera Club, "St. Denys," Bellevue Road, Exmouth.

Patent News.

Process patents applications and specifications—are treated in "Photo-Mechanical Notes."

Applications November 7 to 12 :—

MOUNTING.—No. 30,064. Mounting photographs. W. H. Collins.

COLOUR CINEMATOGRAPHY.—No. 30,207. Colour cinematography. F. W. Donisthorpe.

DRYING PRINTS.—No. 29,650. Drying machines for photographic prints. E. Graber.

CAMERAS.—No. 30,000. Photographic cameras. A. Hayward.

CERAMIC PHOTOGRAPHY.—No. 29,965. Photography upon ceramic ware, etc. F. A Hiorth and W. Spear.

PORTRAITS.—No. 30,069. Production of photographic portraits. G. Hoffman.

STEREOSCOPY.—No. 29,709. Stereoscopic phptography and optical projection. C. H. Piper.

CAMERAS.—No 29,548. Cameras. A. Pittman.

COMPLETE SPECIFICATIONS ACCEPTED.

These specifications are obtainable, price 1/- each, post free, from the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C.

The date in brackets is that of application in this country; or abroad, in the case of patents granted under the International Convention.

FINDERS.—No. 147,107 (April 6, 1915). The present invention relates to the use and modification of a known arrangement, the collimator, as a finder for photographic cameras in a similar way as the collimator is used as a sighting device for firearms (see (*e.g.* Patent No. 17,429 of 1901). According to the invention a collimator is thus connected with the camera without there being disposed in front of the marks of the collimator any collective lenses, producing a real image of the landscape in the plane of the sighting marks. In its simplest form a collimator consists of a collective lens combined with a sighting mark (usually in the focus of the lens) and fulfils the purpose of presenting to an eye located behind the lens or to another optical system a virtual image of the sighting mark, lying at a certain, usually infinite distance. If such a collimator be combined with a photographic camera, a finder is obtained, by means of which the centre of the image to be photographed can be fixed.

The practical construction and further modification of such a finder may be carried out in the following two ways : In the first case the collimator is made as a half lens, so that the field of view is divided into two parts and an eye placed behind the collimator receives as to one half the pencils of light emerging from the collimator and as to the other half those coming from the object viewed ; in the second case the collimator has an entire lens and the observer employs both eyes, projecting the image of the system of marks presented to one eye in the field of view of the collimator, on to the objects lying in front of the other free-viewing eye.

In both cases the value of the finder may be considerably enhanced, by fixing, by means of marks or lines, in a plane approximately coinciding with the focal plane of the collimator lens angular dimensions, which bear a relation to the size of the image produced by the apparatus. As compared with the finder constructions in use hitherto, this has the advantage that the accurate limiting of the size of the image is effected on the object to be photographed itself, and that the image plane is seen, so to speak, in its natural size.

In the usual photographic cameras the lens is generally disposed so as to be displaceable perpendicularly to the optical axis, either only in one direction or in two directions perpendicular to one another. In order that, with such a displacement of the objective, the collimator finder may still bound the correct image field, it is necessary for one of its two component parts

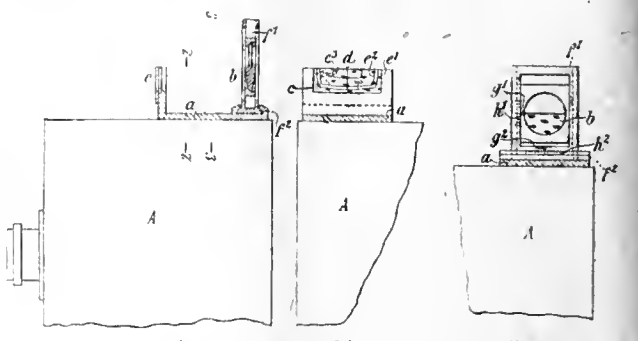

Fig. 1. Fig. 2. Fig. 3.

—lens or mark carrier—to be also displaced to an extent corresponding to the displacement of the objective perpendicularly to the sighting axis relatively to the other part. Hence, the two collimator parts will, corresponding to the manner in which the lens can be displaced, also be made displaceable relatively to one another either in one or two directions perpendicular to one another, the amount of the displacement being preferably read on suitable scales.

In the drawings the invention is illustrated by three constructional examples. Figs. 1 to 3 show a collimator having a half lens in combination with a camera A, the latter being indicated only in outline. Fig. 1 contains a longitudinal section, while figs 2 and 3 each contain a cross-section of the finder. On a bedplate marked *a*, by means of which the finder is fixed to the camera A, there is on one side a half lens *b* and on the other

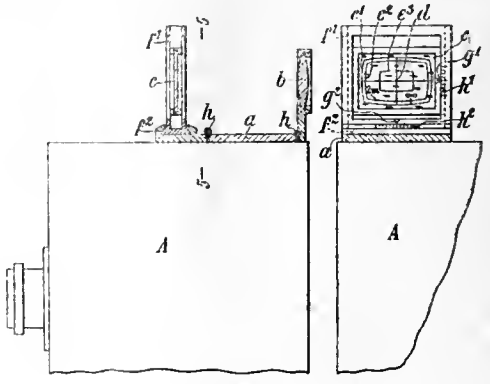

Fig 4. Fig. 5.

side a plane mark carrier *c*, which touches the focal plane of the lens. The mark carrier *c* contains besides a mark *d* fixing the sighting axis two framing lines e^1 and e^2 adjoining the straight bounding line between the free field of view and the field of view of the collimator and corresponding to half the size of the image of the camera used for the objective distances infinity and 2 metres, and also a smaller framing line e^3, which, assuming the camera lens to be symmetrical, corresponds to the angle covered by the back lens alone with an objective distance infinity. In view of the aberrations of the lens, the framing lines are drawn in such a manner that in the field of view of the collimator they appear as rectangles. The lens *b* can by means of two guides f^1 and f^2 be displaced relatively to the

sighting axis in two directions perpendicular to one another, for compensating a displacement of the objective relatively to the middle of the plate. The amount of the displacement in each case can be read off by means of two indices g^1 and g^2 and two corresponding scales h^1 and h^2.

Figs. 4 and 5 show in a similar manner by a longitudinal section (fig. 4) and a cross-section (fig. 5) a collimator finder with an entire lens, i.e., for use with both eyes. The separate parts have the same references as in figs. 1 to 3; the only difference being that the framing lines e^1, e^2 and e^3 now corre-

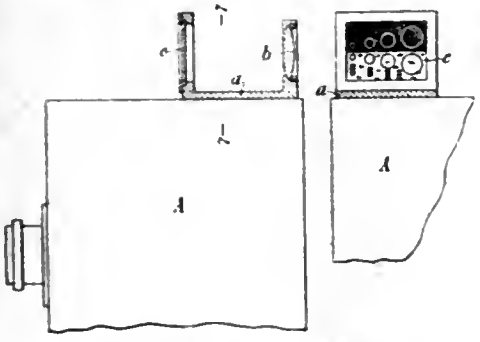

Fig. 6 Fig. 7.

spond in each case to the entire image. In this case the two guides f^1 and f^2 are fitted on the mark carrier c and the lens and the mark carrier can be laid over by means of hinges h.

Figs. 6 and 7 again show a collimator finder with an entire lens. The lens b of the collimator is in this case rigidly fixed to a bedplate a, also a mark carrier c. The frame of the mark carrier forms in this case the limit of the image field. The mark carrier is blackened in its upper half, while in its lower half it is transparent. In each half it is provided with a series of circles, which, getting smaller and smaller, correspond to a spherical balloon of a certain diameter at different distances. At each circle the corresponding distance is marked.—Firm of Carl Zeiss, Carl-Zeiss Strasse, Jena, Germany.

ONE-LENS STEREOSCOPIC PHOTOGRAPHY. No. 170,478 (September 18, 1920). The invention relates to an attachment for stereoscopic photography of the type of that described in Patent No. 21,406 of 1894 of Theodore Brown.

The device consists of a box or casing provided with an opening at the back around which an interchangeable clip or adapter is fixed for the purpose of clamping the device to the lens mount or to the shutter when the same is of the front lens type.

Inside the box and opposed to the opening two reflectors are mounted at an angle meeting on the centre line of the box camera. Two other reflectors are mounted on either side of the box.

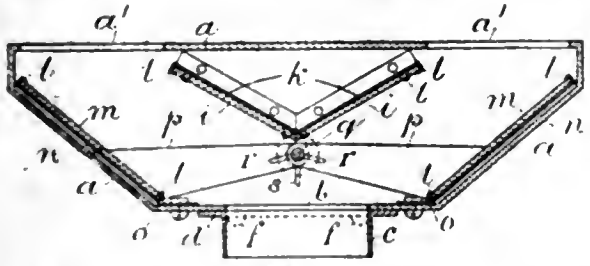

Fig. 1.

These reflectors are coupled together by means of a left and right-handed screw or by levers so that they may be pivoted to or from each other through similar angles.

Opposite these two reflectors the front of the box is left open.

The four reflectors are so arranged that the two right-hand reflectors project the rays from the object through the right-hand orifice in the box to the lens and thence to the left-hand half of the negative and the reverse as regards the left-hand reflectors.

By pivoting the two outside reflectors, objects near the camera can be reflected on to the respective centres of either half of the plate or negative.

As the right-hand reflectors form an image on the left-hand side of the plate and *vice versa* no reversing in printing is required.

The angular setting of the two outer reflectors determines the distance between the centres of the two projected images, the point of view of the images remaining the same so that a stereoscopic picture can be produced with an ordinary vest pocket camera, which picture may then be enlarged in the usual manner to the required stereoscopic size.

Fig. 1 is a longitudinal section of the attachment, fig. 2 is a plan, and fig. 3 is a rear view.

The attachment is constructed essentially after the following manner: A box a is provided in front with apertures a^1 and at its rear surface with an opening b through which the reflection of the object to be photographed passes to the lens and thence to the sensitive plate in the camera to form a picture in duplicate thereon.

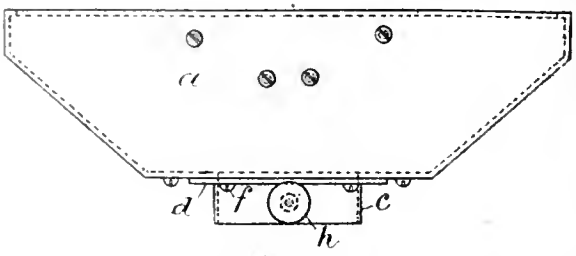

Fig. 2.

For fixing the attachment to the shutter or lens a lens-carrier adapter or interchangeable clip c is detachably fixed around the opening b.

The interior of the box a is furnished with a pair of mirrors or reflectors i set at an equal angle to each other, the apex of the angle thus described being oppositely disposed to the orifice b and in the axis of the lens. The reflectors i are carried in permanently fixed backings k which are provided integrally with bent over lugs l between which the mirrors are inserted and by which they are retained in their angular position. Two other mirrors or reflectors m are mounted within the casing a, each facing one of the mirrors i and are adjustable as to their angular relation to the mirrors i. The reflectors m are carried in backings n and are retained therein by bent over lugs l. The backings n are pivoted at o to the interior of the casing a and are coupled together either by means of a left and right-hand threaded screw and coupling rods or by levers p integrally formed with the backing as shown. The levers p are coupled together in the vertical axis of the device by means of a clamping pin q which passes through a slot r formed at the extremity of each lever. The clamping pin also passes through a slot s formed in the casing a and is furnished with a serrated clamping knob or button for the purpose of clamping the mirrors m at the desired angular

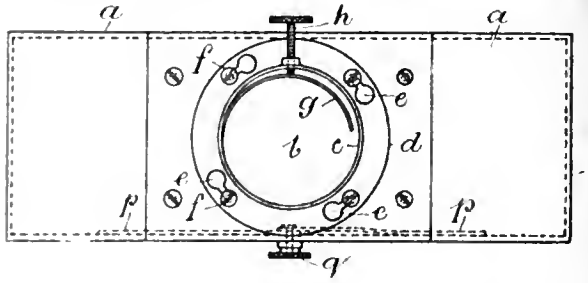

Fig. 3

relation to the opposing mirrors i for the purposes hereinafter detailed. The reflectors are so arranged that the opposing pair on the right hand side reflect the rays from the object being photographed through the right-hand orifice a^1 of the casing to the casing to the left-hand side of the plate or negative within the camera and the reverse as to the left-hand reflectors which obviates the necessity for reversing the pictures in the process of printing.

As the angular setting of the pivoted reflectors m determine the distance between the centres of the view of the two projected images, the point of view of the images remains the same, so that stereoscopic pictures can be produced on a small scale with even a vest pocket camera, which can afterwards be enlarged to the ordinary stereoscopic dimensions.—William Henry Boothman, 5, Princes Square, Bayswater, London, W.2.

New Apparatus.

OSGLIM ELECTRIC LAMPS.—An entirely new type of electric bulb has been introduced under this name by the General Electric Company, Magnet House, Kingsway, London, W.C.2. No filament is used, but a glass bulb of the usual shape contains two metal electrodes (anode and cathode) in an atmosphere of the rare gas Neon. Special features of the lamp are the great durability of the electrodes, which are of stout wire, and the very low current consumption, which is only 5 watts. The light given by the lamp is a dim illumination, quite sufficient for passages or dark portions of premises where it is necessary to keep some light constantly burning. Moreover, the peculiar distribution of the light gives exceedingly diffused illumination. The lamps are also supplied in a so-called "letter" pattern, the cathodes being shaped in the form of the various letters of the alphabet. Thus, by means of a few of the letter lamps any required illuminated sign may easily be made up. In the ordinary pattern the price of the lamp is 4s. 6d.; in the letter pattern 5s. The lamps are at present obtainable for voltages ranging either from 200 to 220, or from 221 to 250. It is also necessary to specify whether the current is direct or alternating. With direct current the lamp must be placed in the holder so that the charge passes in the correct direction, i.e., from the anode to the cathode. If inserted in the holder in the other position the lamp is in no way damaged but the maximum amount of light is not obtained.

New Books.

"Penrose's Annual" (The Process Year Book). Vol. 24. Edited by William Gamble. London: Lund, Humphries and Co., Ltd. 8s. net.

WE look each year to the "Process Year Book" for a record and demonstration of the progress which is being made in methods of photo-mechanical reproduction, and in other applications of photographic methods to the art of the printer. And Mr. William Gamble does not disappoint us in either of these respects. His review of process work is in a minor key, since there is little to record in the way of epoch-making introductions. In ordinary line, half-tone, and three-colour reproduction, practice continues to follow the customary lines; activity is chiefly shown in the surface printing processes, and more especially in photo-litho and offset printing. Rotary photogravure continues on its way, and the "Year Book" contains some excellent examples of colour work by this method.

We are interested in reading of the attempts which continue to be made in replacing type-setting by processes in which a lay-out of the required lettering is reproduced by photographic methods. Mr. Gamble directs attention in this connection to the patent, No. 7,097, of 1895, taken out by the late Mr. Friese-Greene for a process of this description. It affords another instance of Friese-Greene's inventive genius, but like other ideas from his fertile brain it failed to achieve financial success.

Contributors to the "Year Book" are comparatively few in number, but there are a number of articles, a fair proportion of which deal with new processes in which the writers are commercially interested. It would, we think, be well if any such interest were more explicitly stated at the head of the article than is done in some cases. But, after all, perhaps the chief value of the volume as a record of progress in process, is the collection of supplements illustrating the current standard of work in various processes. These form a section of the "Year Book," which fully maintains its interest. The specimens include up-to-date work in half-tone and three-colour, photogravure in monochrome and colour, and other methods of reproduction. It is perhaps of some significance that a careful examination of these plates shows that the colour reproductions, which appear most truthful, or are made for the illustration of scientific publications, are printed in four colours. Altogether the 1922 "Process Year Book" worthily takes its place with the many volumes which have preceded it.

THE WELLCOME EXPOSURE DIARY AND CALCULATOR.—The tireless compilers of the ever-popular Wellcome diary contrive each year to add some new and useful feature to this pocket volume. For the 1922 issue, which has just been published, the chief addition is an indication in the table of plate speeds of the development speed of each of the many makes and grades of plate and film which are specified. These are designated by letters running from A. to N., which symbols correspond with the times which must be allowed for development at various temperatures as set out in other tables in an earlier part of the book. In other words, Messrs. Burroughs Wellcome have taken a useful step towards making development as easy and certain a system as their calculator has made exposure. On another page also is a table giving the volume of developing solution required by the various tanks on the market for the development of plates and film. Another new feature is a chapter on selling photographs for reproduction, which contains the scale of fees adopted by the Professional Photographers' Association. The little book is so widely known among amateur photographers, and doubtless among many professionals also, that it is not necessary to recapitulate the many items of practical instruction which its pages contain. It should be mentioned that as in previous years three editions are issued, one for the Northern Hemisphere and Tropics; another for the Southern Hemisphere and Tropics, and a third for the United States.

ROYAL PHOTOGRAPHIC SOCIETY.

Meeting held Tuesday, November 22. The President, Dr. G. H. Rodman, in the chair.

Mr. A. C. Braham, of the Autotype Company, gave a demonstration of the latest developments and improvements in the Carbro process. He alluded briefly to the derivation of the process from Ozobrome. In Carbro, the pigment tissue is soaked in a solution of potass. bichromate, ferricyanide and bromide, allowed to remain for a short time in a bath containing acetic and hydrochloric acids and formaline, and then squeegeed in contact with a bromide print. After about 15 minutes the bromide is removed and the tissue (which now bears an invisible image of insolubilised gelatine) squeegeed to transfer paper. The original paper base of the tissue coating is then stripped off, and the picture developed in hot water, yielding a carbon or "Carbro" print.

Whilst giving an excellent demonstration of the process, in the course of which he made two prints, Mr. Braham first emphasised the importance of soaking the bromide print thoroughly. The temperature of the two baths for preparing the tissue should be from 60 deg. to 65 deg. F. The first bath (of bichromate, etc.) could be kept in use indefinitely, renewing it with fresh stock solution from time to time, but it should be strained through muslin before use. The tissue was soaked in it for about 3 minutes and then drained for about 15 seconds.

The time of immersion in the second (acid) bath provided the means of modifying the contrast in the Carbro print; the longer the time, the softer the print. A normal time for producing a print of the same contrast as the bromide was 20 seconds.

After squeegeeing the prepared tissue to the soaked bromide print, the pair were laid on glass and covered with grease-proof paper, thus obviating evaporation of the solution and absorption of it during the period of its action on the bromide. After removal of the bromide and transfer, the picture was developed at a rather lower temperature than customary in ordinary carbon printing.

While these processes were being carried out, Mr. Braham answered a string of questions. A print of gaslight paper never gave as good a Carbro print as one on bromide paper. He had not tried the suggestion of Dr. Slater Price, viz., of bleaching a gaslight print to a silver bromide image and re-developing before using it for the process. Different makes of bromide paper required different times of the tissue in the acid bath. On the other hand, different colours of tissue, with the exception of red chalk and olive green, required the same time in the acid bath.

He showed the results of provisional experiments made to prepare a retouching mixture which could be used on bromide prints employed in the process. He had mixed Indian ink and fish-glue with "silver" obtained by adding caustic soda to silver nitrate solution. The retouching marks reacted with the No. 1 preparing bath, and were reproduced in the Carbro print.

Mr. Braham had had no experience of the process in the making of oil prints. As regards quality of the Carbro prints, he was fully satisfied that it was equal to that obtained on light-sensitive tissue printed directly from negatives according to the regular carbon process.

On the proposition of the chairman, the very hearty thanks of the meeting were accorded to Mr. Braham.

CROYDON CAMERA CLUB.

In the opinion of the Croydonians nothing but good comes out of Richmond, and last week Mr. F. R. Newens found an excellent attendance when he arrived with a heavy box of slides to give a lantern lecture, entitled "Rambles with the Paget Colour Plate." Reassured by his previous visit, this time he came unarmed. Now, a short time ago the ground-floor caught fire and gutted the landlords' premises below. Being landlords, little in the way of sympathy would be expected on modern ethical principles, but real interest was aroused when it was found last week, and at the last moment, that some "repairing" electricians, before leaving, had effectively cut off the electric supply to the club, and in consequence the lantern would not be run. This put the secretary in a nice temper, and the "office boy," who pleasantly wished him "Good evening," immediately became conscious of the offence.

Everything, therefore, pointed to a fiasco, but to do the club justice rarely is it at a loss, whatever the contretemps. Mr. Newens was placed on his legs and chatted instructively and interestingly about procedures; the slides were taken as seen, and a brisk discussion brought a capital evening to a close.

It is not necessary to follow the lecturer through his clear exposition of the process, and only a few points raised need be summarised. Should a bit of grit or broken glass get in between the plate and taking screen, he said, this may be recognised by bars of colour appearing when attempting registration. Also, sometimes little pieces of the emulsion may stand up at the edges of the plate and prevent good contact with the taking screen. To avoid this, he runs a very sharp knife round to remove any protuberances. In some cases, instead of the orthodox filter he uses a Sanger Shepherd graduated one, and secures a nice blue sky, with good colour reproduction throughout, but this variation in procedure requires very great care.

During the war when at one time Paget plates were unobtainable, he substituted Ilford panchromatics, employing a film light yellow-green K ½ filter (who made it he could not say). The results were fairly good and exposures much reduced. It should not be overlooked, he added, that the Paget panchromatic and transparency emulsions are coated on glass specially picked for flatness, and if only for this reason substituting other plates is not to be recommended.

Inasmuch as both Messrs. Ilford & Wratten issue cards with each box of panchromatic plates, giving the ratio of sensitiveness to the three primaries, he deduced that a uniform ratio is impossible to attain, and, this being so, he suggested Messrs. Paget should stock a series of gelatine filters, and on request select one best fitted for any particular box of plates. For the serious worker this would be a great boon.

For estimating exposures he much prefers the tables of Messrs. Burroughs Wellcome to any tint-matching meter, and gives half as much again as the readings indicate. The weak point of the Paget plate is in the greens which are apt to be too blue. Full exposure usually corrects this tendency. Though occasionally, when sorely tried, he had muttered "somethings" about the Paget firm, yet it had accomplished much, and should be congratulated on the production of a product which must present many manufacturing difficulties.

In the discussion, Mr. Harpur said he invariably used the tables mentioned in his ordinary photographic work, and found them accurate under all conditions. He then passed on to a genial patchwork review of various matters, and dexterously included some shrewd blows at Mr. Salt. The latter, in acknowledging this attention, said that having regard to the long photographic experience of Mr. Harpur, the fact that he was still compelled to consult exposure tables on all occasions was extremely painful to hear—not only painful but pitiful. Many others contributed to the discussion on saner lines, and the proceedings terminated with a hearty vote of thanks to the lecturer.

GELATINE FIXATIVE FOR ENLARGEMENTS.—A French professional photographer, M. Bourland, of Périgueux, in "Le Photographe," remarks on the difficulty of using a solution of gelatine with the air-brush as a means of obtaining a fixative coating on worked-up enlargements, owing to the tendency of the solution to run into drops on the print. This defect, M. Bourland states, can be avoided by adding a proportion of alcohol to the gelatine solution. An equal volume of alcohol may be added to a 1 per cent. solution of gelatine if the latter is meanwhile kept warm on a water-bath, and the mixture constantly stirred whilst the alcohol is added in small quantities. The solution will then remain liquid after cooling.

News and Notes.

A PHOTOGRAPHER'S WILL.—Mr. Thomas White, a former Mayor of Lewisham, and photographer, left estate of the gross value of £1,364 5s., with net personalty of £230 5s.

THE MARRIAGE took place on Saturday last, November 19, at St. Nicholas Church, Chiswick, of Ernest W. Taylor, only son of Mr. and Mrs. J. Hay Taylor, of Palmer's Green, and the only grandson of the late J. Traill Taylor, to Winifred L. Collins, elder daughter of Mrs. Arthur Collins, of Netheravon Road, Chiswick.

D.50 DEVELOPER.—The Cooper Laboratory, Watford, is making a special offer to photographic dealers in connection with its D.50 developer. Until December 16 it offers to include with every order to the value of £1, and also with every order amounting additionally to £1, two 2-oz. bottles of D.50, each priced at 2s. 6d. It also offers in the same proportion one dozen special trial samples of D.50 for distribution among dealers' customers.

PENNSYLVANIA STATE COLLEGE.—We regret to hear that the laboratories of the Photographic Division of this College were destroyed by fire on October 28 as a result of an outbreak in another part of the building. Every piece of equipment was destroyed, although fortunately most of it was covered by insurance and can be replaced. A new research laboratory, which had been opened only on the morning of the fire, was also destroyed. It is feared that the apparatus in this laboratory cannot be replaced for a long time except by the assistance of other institutions. The director of the Photographic Division, Mr. Carrol B. Neblette, will have the sympathy of all those interested in photographic instruction, and, we hope, the help of those able to make good some of the loss which has been sustained.

INVENTION OF AERIAL CAMERAS.—Before the Royal Commission on Awards to Inventors last week, Lieut.-Col. J. T. C. Moore-Brabazon made a claim in respect of aircraft cameras. Mr. Carthew, for the claimant, said Col. Moore-Brabazon was a pioneer in aviation, and was also interested in photography, and early in 1915 he was appointed a wing photographic officer in France. In the early type of cameras the plates had to be changed singly after each exposure, this operation taking twenty or thirty seconds. Col. Moore-Brabazon conceived the idea of designing a camera which would automatically perform the necessary change of plate, and, at the same time, wind up the focal-plane shutter. A magazine containing eighteen plates was placed on the top of the camera, there being another fixed underneath into which the exposed plate dropped Col. Moore-Brabazon took his designs to Messrs. Thornton-Pickard, who made models, and the invention proved an enormous success The principle was adopted by the French and the Americans, and the Germans were at a great disadvantage because they never had anything like it. The plates could be changed in two or three seconds, enabling photographs of a continuous line of trenches to be taken as well as stereoscopic photographs. The claimant asked for an award of £10,000.

It was stated that Messrs. Thornton-Pickard had taken out a patent in connection with the invention, but that they made no claim as they considered they had been sufficiently remunerated under the contracts they had carried out.

At an adjourned hearing, Mr. R. Hesketh, formerly secretary of the Thornton-Pickard Manufacturing Company, gave evidence of the cost of the production of certain cameras, and the amount the Government were charged for them. The firm took out a patent for the "O" camera in August, 1915. Later witness had a conversation with Major Campbell, who was then officer in charge of the Air Department, dealing with photography. Major Campbell was very angry about it, and said the firm had no right to take out the patent, because the invention, if it belonged to anyone, belonged to Col. Moore-Brabazon.

Col. Moore-Brabazon said it might sound rather absurd, but when aerial photographs were originally taken they were not very welcome at headquarters. He added that later there was a cry for photographs, and there was a desire for a quicker way of taking them. It was then the idea for the invention occurred to him. Witness also spoke of his visit to England, and to the Thornton-Pickard Company, and gave a demonstration to the Court of his invention.

Asked why he did not write to the firm protesting against their taking out a patent, witness said he complained to Major Campbell.

Mr. Trever Watson, for the Crown, said he was satisfied to accept Col. Moore-Brabazon's evidence as being entirely correct, and there was no need to pursue the matter further. Explaining the attitude of the Treasury, Mr. Watson said they had a statement from Mr. Gray Pickard, in response to an inquiry, which stated categorically that the invention was Mr. Gray Pickard's. That being so, and the fact that Mr. Pickard was not called, it became the duty of the Crown to probe into the matter. Having heard the evidence, they were satisfied the letter had been written under a misapprehension, and they accepted what Col. Moore-Brabazon had said.

Mr. Justice Sargant said there was the greatest difficulty in giving a claimant an award in respect of an invention which had been fully paid for by the Government so far as the cameras had been used. What the Commission proposed to do was to adjourn the application for some considerable time, in order to give Col. Moore-Brabazon an opportunity of taking such proceedings as he might be advised

FOREIGN PHOTOGRAPHIC LENSES.

To the Editors.

Gentlemen,—The letter from Mr. K. C. Browning on "Foreign Photographic Lenses," in your issue of the 18th inst., is very interesting, but is far from being conclusive.

He simply takes one Goerz lens and compares it with one English lens, and also quotes the results of tests of an English telephoto lens.

It would be much more satisfactory if a number of lenses, say about a dozen, could be taken at random from each of the leading English and Continental makers, and tested at the N.P.L., and the results published. The results of the comparative tests of individual lenses are apt to be very misleading when making general comparisons.

I hold no brief for foreign lens makers, but I have a Goerz lens, purchased pre-war just in the ordinary way of business, and I have not yet seen another lens to equal it, although I have handled a great many since that time.

In recent years I have purchased a number of lenses from English makers, and the result of my experience goes to show that although makers of lenses, both English and foreign, are not backward in claiming what their lenses are supposed to do, yet they do not always take the necessary care to ensure that their lenses are up to the standard advertised before they are supplied to purchasers.

One illustration will suffice. I ordered a lens from an English maker for a ¼-plate camera, the front of which was provided with the usual vertical and cross movements. When ordering, I stipulated that the lens should be tested at the N.P.L., and that the Class A certificate should accompany it. This was arranged on the understanding that I paid the cost of testing, etc., and I agreed to do this.

In due course the lens arrived, without the certificate, and as the covering power did not seem satisfactory, I posted the lens to the N.P.L. for examination. I subsequently learned that the lens had been previously tested, but although it was advertised to cover a 5-in. × 4-in. plate at full aperture, intimation was sent by the

makers that it was only to be used on a ¼-plate, and it was therefore only tested for that size of plate.

The lens would not satisfactorily cover a ¼-plate unless stopped down to *f*/8, although the full aperture was *f*/4.5, and a Class A certificate for a 5-in. × 4-in. plate was not obtainable.

On communicating with the makers, I had considerable difficulty in getting another lens, and only did so after waiting several months, although this incident occurred during the past two years.

It has often been advised in the photographic Press that purchasers of high-class lenses should have them tested at the N.P.L. before accepting them, but photographers generally, and particularly amateurs, do not seem very willing to take such trouble.

The two principal requirements of a lens for the ordinary amateur are definition and covering power, and these are always guaranteed by the makers.

It appears to me that the solution of the whole difficulty is in the hands of the makers. If the makers are satisfied that their productions are equal to what is claimed for them, why not send all lenses above £2 or £3 in value to the N.P.L. for test, and issue a certificate with each lens given by that Institution, showing that, so far as definition and covering power are concerned, the lens will do all that the makers advertise for it. I feel quite sure that the purchasers would generally be quite prepared to defray the cost of the certificate, and, if this were done, a large number of lenses would require testing, and no doubt a simple certificate at a small cost could be obtained.

It is a most unpleasant business to write to lens manufacturers and tell them that the lenses supplied by them are not up to their advertised standard.

I believe that a great number of "would-be" photographers are discouraged through getting a bad lens to start, when they paid for a good one, and frequently give up photography in disgust, thinking that the trouble is with themselves.

If nothing but lenses up to advertised standards were issued, I feel sure there would be more photographic enthusiasts, and the whole trade would be benefited.

Perhaps other readers of your paper may have views on this subject, and it would be interesting to know how far the lens makers would be prepared to go in this direction, to prove without question the absolute superiority of the English-made lenses.

I attach my name and address, but shall be obliged if you will not publish it.—I am, Gentlemen,

Yours faithfully,

"AMATEUR."

November 21.

[A letter from Messrs. Peeling and Van Neck on this subject, received as we go to press, is held over until next week.—Eds., "B.J."]

A CONTRAST RATING FOR PRINTING PAPERS.

To the Editors.

Gentlemen,—May I trespass on your space to reply to Dr. Glover's criticism of the suggestion for a contrast rating for development papers? I cannot see that it is unlikely for a request for a similar degree of contrast to bring anything capable of giving similar results. On the contrary, I am in the practice of handling seven grades by three makers, and though they are very constant I find at times fluctuations in the vigour of most of them.

When dealing with thousands of negatives per day, and often against time, it is utterly impossible to measure the gamma of any of them; nevertheless, a change in the vigour of a paper that is used for a class of negatives is felt in the general quality of the output, and this is an important thing with business photography. As regards the different qualities of papers having the same contrast that is only to be expected. The same thing applies to plates—some having longer straight line periods of their curves—but it is no argument for dropping H. & D. numbers. Admittedly a contrast rating, or even a rough description, is not indispensable when making amateur studies. For this purpose I usually take a selection of papers and mess about till I get a result that pleases me, irrespective of the nature of the paper. I would just as soon use plates that were merely marked "Slow" or "Fast," not being tied to an experimental negative or two. Some of the most satisfactory results I have had have been quite unexpected in view of the class of materials used and the particular uses. But this is a very different thing to commercial practice where a standard result is expected almost mechanically.

When it is considered that yourselves, *The Photographic Dealer*, *American Photography*, Messrs. Criterion, Illingworth and Wellington and a number of professional printers have shown interest in the idea—though not all in absolute agreement—it is hard to see how it can be "fading into insignificance." Rather it is likely to fructify.

It is true that photographers can make their own charts to enable them to arrive at a correct idea of the papers' nature, but some order by the hundred gross, and we might prefer to know the degree of contrast before getting orders consigned or deliveries put into use.

Numerous photographers do not use soft Velox, and I fail to see how any paper could be set down as a standard for all others. They might all fluctuate slightly (with all due respect to makers).

Dr. Glover evidently is not *au fait* with the commercial atmosphere of photography, but, even so, our thanks are due to him for helping to bring this question into the daylight.—I am, yours sincerely,

J. R. HALL.

31, August Road, Liverpool, E. November 19, 1921.

To the Editors.

Gentlemen,—I am surprised that a gentleman of Dr. Glover's standing should waste his time on a letter of the kind that appeared in your issue of the 18th inst. His own arguments condemn him. He starts off by trying to prove that the method of contrast rating for bromide and gaslight papers suggested by Mr. Hall and myself is unscientific and unnecessary, and then calmly goes on to suggest a method for testing papers which at the very best can only be called 'rule of thumb." Granted that contrast numbers will not tell the printer all he wants to know about a paper, they are, nevertheless, likely to be extremely useful. No one would suggest for a moment the H. and D. numbers on plate boxes give a very precise idea as to the performance of any particular brand of plate, but they are not necessarily to be despised on that account, though possibly Dr. Glover would like to see those abolished and each operator left to work out his own salvation with only such names as "special rapid," "special sensitive," "extra speedy," etc., as a guide.

Dr. Glover talks very learnedly about characteristic curves and gamma infinity, and these things are quite right and proper in their proper place, which is the laboratory, but they have little practical value in the printing room; and even if the average assistant printer knew much about these things (and we all know that he does not as a rule), he would have little time to bother with them in the course of a day's work. I wonder if Dr. Glover has ever had to turn out two or three thousand prints a day, or has had the job of supervising a large staff of assistant printers—mostly unskilled girls? If so, he would appreciate even a small help towards the standardisation of materials.

I have no wish to appear personal, but at the same time there are times when I wish some of our learned theorists, whose labours in the research laboratory we thoroughly appreciate, would occasionally descend from their pedestals and look at things from the point of view of the man who has to get the work done.

It would be interesting to have the opinions of a few practical workers on the subject.—Yours faithfully,

H. TAYLOR.

Commercial & Legal Intelligence.

ILFORD, LIMITED.—Messrs. Ilford, Ltd., have declared a dividend of 8 per cent. on the ordinary shares for the year ended October 31. The dividend for 1919-20 was the same.

Answers to Correspondents.

In accordance with our present practice a relatively small space is allotted in each issue to replies to correspondents.

We will answer by post if stamped and addressed envelope is enclosed for reply: 5-cent International Coupon, from readers abroad

Queries to be answered in the Friday's "Journal" must reach us not later than Tuesday (posted Monday), and should be addressed to the Editors.

C. F. Watkins.—"Le Photographe," 35, Boulevard St. Jacques, Paris XIVe

C. J.—There is no recognised proportion between the price charged for single portraits and that for groups. Perhaps the best indication we can give you as regards prices for groups is the schedule adopted by the Edinburgh Society of Professional Photographers.

H. A. Aylward.—Copper will stand a great deal of wear, but is liable to get into an unpleasantly corroded state unless more than ordinary care is taken to clean out the tank and wipe it dry when it is not in use. For quantity development of cut films, a well-made tank of hard wood, with or without lead lining is much preferable.

Van Ralty, Ltd.—Under the Shops Act the parts of a photographer's establishment usually open to the public must be closed to the public on the weekly half-holiday, but it has been held that portraits may be taken of sitters with whom appointments have been arranged previously. The distinction is that you must not have the shop open for any passer by to come in.

S. F.—The best thing you can do is first to remove the retouching medium with turps or ether, wash for a few minutes, and then soak the negative in a weak solution of soda carbonate, or ammonia. This will take away all the uranium intensification. If it is intended to re-intensify with uranium, the negative should be well washed and soaked for a few minutes in a weak solution of acetic acid before re-applying the uranium mixture.

M. T.—We suppose your query relates to English translations. In that case Dr. Eder's book has been out of print for many years. You might get a copy from Messrs. Foyle, 121-123, Charing Cross Road, W.C.2, or Messrs. Sotheran, 140, Strand, W.C.2. So far as we know the only book by Valenta on emulsions is on P.O.P. emulsions, but has not been translated into English. For this you should apply to W. Knapp, Halle a/S, Germany.

B. W.—We are interested in seeing the negative (returned). It is quite a normal uranium intensified negative. Evidently the rebate of portions of the negative had a veil over them, which accounts for the brownish deposit there. But if you had had a trace of hypo in the film you would have got an utterly useless result in consequence of patches. We think the negative has the normal uranium image, and we do not think you would make it any better by trying to clear it with sulphocyanide.

W. K.—Your proposed installation of six (1,000 c.p.?) half-watt lamps with a maximum height of 8 ft. to the filaments, would be quite practicable. The heat would not be unpleasant and the reflection from the ceiling would be rather an advantage than otherwise. Keep the ceiling white. It would be well to have, say, four of the lamps to raise and lower, as you would often want to use them for sitting figures and babies, as by this means you could halve your exposures. We should not recommend movable stands in a room only 14 ft. wide, as they would take up a lot of space and prevent your getting a front light for large groups. As far as the length of studio is concerned, 42 ft. is ample for any class of work. Have a black curtain lined with white behind the lamps and a thin muslin or cheese cloth on in front. Keep these at least 9 in. from the bulbs, or they may get scorched.

M. S.—Eighteen feet is rather too short for full-length figures, so that you will have to provide a short focus lens for these, say, one of 8½ inches focal length for cabinets, otherwise the size of room is quite suitable. It is quite impossible to give an estimate of the total cost of equipment, so much will depend upon the size of direct negatives you intend to work, also whether you buy new or second-hand apparatus. We find it more usual for beginners to allot the sum they can afford, and to do the best they can with it. We suggest that you could make a start with a whole-plate camera and use an enlarger for any large sizes. You should be able to get all that is really necessary for £100 to £150, excluding furniture, which, however, is not much used in modern work. If you intend to instal electric light the cost of lamps and wiring will be about from £25 to £50 in addition.

H. J. C.—The only practicable process for the purpose you name is collotype, but we are quite sure that the equipment and the time required to obtain competency in the process would make the cost of the reproductions greater than that which would be incurred in having them printed by a firm which does collotype for scientific purposes, or by making actual bromide prints. If you wish to do the work yourself we think bromides would be much the cheapest in the long run. Three-colour reproduction involves making half-tone blocks and requires a practical training, such as can be got at the L.C.C. School of Photo-Engraving, 6, Bolt Court, E.C., in all photo-mechanical processes. There is a text-book by W. T. Wilkinson, published by Messrs. Hamptons, Cursitor Street, W.C., entitled "Photo-Mechanical Processes," and priced at 4s. 6d., but no one expects to do very much in these methods only by self-instruction from books.

P. P. K.—The Zanot formula is for the toning of development prints; that is, bromide or gaslight, not for P.O.P. The "Artura" referred to is a development paper made by the Eastman Kodak Company in America, but so far as we know is not on sale in this country. The following is the formula for the "B.J." pyro soda:—

Make up two solutions according to the following formula:—

A.—Pyro	1 oz.	50 gms.
Soda sulphite, cryst.	8 ozs.	400 gms.
or anhydrous	4 ozs.	200 gms.
Potass. metabisulphite ...	1 oz.	50 gms
Water	60 ozs.	3,000 c.c.s.
B.—Soda carbonate, cryst. ...	12 ozs.	600 gms.
or anhydrous	4½ ozs.	225 gms.
Water	60 ozs.	3,000 c.c.s.

Mix A, 1 part; B, 1 part; water, 2 parts.

In making the A solution the sulphite and metabisulphite should be mixed together dry and put together into hot water When they are dissolved, the solution should preferably be brought to the boil and boiled for about a minute, after which the pyro is dissolved—when the solution is cooled. The boiling greatly improves the keeping qualities of the solution.

If preferred the sulphite and metabisulphite can be dissolved in only half the water and the necessity of heating or boiling so much solution thus avoided. The second half can be added cold and the pyro then dissolved.

JOURNAL OF PHOTOGRAPHY.

No. 3213. Vol. LXVIII. FRIDAY, DECEMBER 2, 1921. Price Fourpence.

Contents.

SUMMARY.

It is announced that the Photographic Fair at the Horticultural Hall next year will be held from May 1 to May 6. (P. 713.)

Mr. Arthur C. Brookes's intimation of his arrangements for the Fair contain the first particulars to be made public that the Professional Photographers' Association intend to hold next year's Congress in the early autumn. (P. 713.)

Particulars of his process of photo-sculpture, on which Mr. H. M. Edmonds will lecture at the R.P.S. next Tuesday, are given in a patent specification on page 718.

Mr. W. T. Wilkinson, in "Photo-Mechanical Notes," gives practical instructions and formulæ in the making of multiple negatives for photo-litho printing. (P. 716.)

Messrs. W. J. Smith and E. L. Turner describe a calculator for ascertaining the relative time of exposure, when photographing originals, according to the distance of the arc lamps and the angular position of the latter relatively to the copy-board. (P. 717.)

Mr. F. C. Tilney reviews the collection of portraits by D. O. Hill, Mrs. Cameron and Rejlander, which are being shown at the house of the Royal Photographic Society, together with some modern pictorial by a South African photographer, Mr. Elliott, of Cape Town. (P. 717.)

Formula for a developer, which is said to black prints yielding better sepia tones with hypo alum, is the subject of a paragraph on page 714.

The wide field which remains open for advertisement photographs of pictorial quality is emphasised by an account of the aims of an American professional who has made work of this kind his specialty for many leading advertisers. (P. 715.)

Some guidance to the less experienced in the business of studio portraiture, among the conflicting counsels of "art" and ordinary work, is given in the course of a leading article on page 714.

"COLOUR PHOTOGRAPHY" SUPPLEMENT.

In a contributed article, Mr. R. M. Fanstone describes his procedure in using the chromium intensifier for Autochromes. (P. 45.)

A description of a three-colour camera, recently designed by Mr. A. Roland Trist, is given by Mr. W. Penrose Gamble in "Penrose's Annual." (P. 48.)

Mr. E. J. Wall has disinterred an interesting account of the experiments made for Clerk Maxwell by Thomas Sutton, from which it is seen that Clerk Maxwell's process in practice was a four-colour one. (P. 47.)

The optical arrangement for a two-colour process of cinematography, invented by Giovanni Casieri, is described in a recent patent specification. (P. 46.)

The idea of illumination of the original by particular non-overlapping sections of the spectrum has been revived in a recent patent. (P. 47.)

Mr. F. E. Ives writes in reference to his priority in the invention of various processes and apparatus for colour photography. (P. 48.)

EX CATHEDRA.

The Fair, May 1 to 6

The prospectus, just issued by Mr. Arthur C. Brookes, informs us that the Photographic Fair will be held next year at the Horticultural Hall, from Monday, May 1 to Saturday, May 6. This is a period which is shorter by two days than that during which the Fair remained open in the spring of the present year, but the requirements of the Royal Horticultural Society for its own exhibitions are the reason for the shorter time which will be available next year. The Congress of the Photographic Dealers' Association will be held during the period of the Fair, and arrangements are being made by that body to make its Congress a much more important function than was the case this year, when the threatened general railway strike in support of the Miners' Federation played havoc with the carrying out of the programmes of all meetings falling about that time. It will, in fact, be remembered that this year's Fair opened on the very day when a general paralysing strike was at any rate probable. Better counsels, however, prevailed in the labour world, and the Fair, which had opened with such black prospects, proved an immense success, and, by the crowds of the public which thronged it from morning till night, justified the steady optimism of Mr. Arthur C. Brookes during the days preceding its opening.

* * *

—and the P.P.A.

But it will surely come as a great surprise to members of the Professional Photographers' Association to learn from the prospectus of the Fair that its Council has recently decided not to hold the Congress of members and the exhibition of professional portraiture at the Fair. Mr. Brookes, who must be fully informed of the change of arrangements, states that the early part of September next year has been decided upon for the holding of these functions. We have no further information from the Professional Photographers' Association in regard to this matter, beyond the brief intimation contained in the report of a meeting of the council held on November 11 last, which appears on another page, to the effect that as the year 1922 is the twenty-first anniversary of the foundation of the Association a special effort is to be made to make the Congress and exhibition an advance upon all previous ones, and that new features of up-to-date interest to professionals are to be introduced. It is further stated that after a lengthy discussion further consideration of schemes for this purpose have been deferred to a succeeding meeting. We must wait until a definite announcement is made before we can form a complete opinion upon the wisdom of the proposed break. From the meagre facts at present available it must, however, be supposed that the advantages attaching to an autumn Congress are very considerable indeed in order to justify abandon-

ment of those derived from association with the Fair. The opportunity of taking part in the Congress and of visiting the Fair by one single visit to London is a feature of the old arrangement, which, we think, was a very great element in the success of the former. Professional photographers will still wish to see the Fair, at which features of special interest to them will be provided, and it remains to be seen whether those in the Provinces will make a second visit to London during part of the holiday season. The P.P.A. should announce its revised programme without delay and should state if it is definitely committed to it.

* * *

Iodide and Hypo-Alum. Difficulty in getting satisfactory sepia tones with hypo-alum is one of the old-standing complaints which constantly reaches us. It would almost seem that many papers are now less amenable to this method of toning than was formerly the case. It may, therefore, be of interest to quote a formula for the developer of the black print which is found to facilitate the production of a good sepia tone in the hypo-alum. Writing in "Camera Craft," Mr. W. H. Emmet recommends the following:—Amidol, 25 grs.; soda sulphite, anhydrous, pure, 150 grs.; potass iodide, 10 per cent. solution, 40 drops; water, 10 ozs. This developer is used without bromide, and while it is recommended for Velox paper, the iodide is stated to have a certain effect which is favourable to the action of the toning mixture. We hear also that iodide, in the form of silver iodide, is being recommended as an addition to the hypo-alum toning solution itself, and thus it would seem that iodide, in one form or another, exerts a certain beneficial effect upon the process, although in what way this effect is produced we must confess that we are unable to say. A factor in the process, which is sometimes overlooked by those in difficulties, is the quality of the original negative. With negatives which are deficient in vigour it is difficult to obtain satisfactory hypo-alum tones by any modification of the original developer of the prints or of the toning bath itself.

SIMPLICITY IN PORTRAITURE.

There is no law written or unwritten to dictate to the photographer what style of work he shall issue, but in most cases he will find it more profitable, and in the end quite as pleasant, to ascertain the requirements of his customers and do his best to meet them. Naturally, these requirements vary to a very great extent in different localities and among different classes of customers, and what is acceptable in one case will not be so in another.

The young photographer who takes as his standard much of the exhibited work of those whom we may truly call photographic artists, a much ill-used term, will often be disappointed to find that quite meritorious work in what we may call the modern style is coldly received by the public, who, as a rule, come to him for a clearly-defined portrait and not the more or less artistic impression of the photographer. A word that is often dinned into one's ears is "clear," and this gives the key to success in the portraiture of average persons. As was pointed out by several correspondents a few weeks ago many successful photographers have displayed totally different classes of work in their showcases and the exhibitions, thereby showing their business acumen, but not all are so wise. We can recall the case of one very clever operator who had met with great success while carrying on the traditions of an old-established studio in the provinces, but who tired of the class of work which had yielded him more than a competence, and came to London determined to devote himself to artistic portraiture only. He had no society influence, which might have made him a success of the moment, and in a couple of years his means were exhausted and he had to retire into obscurity. His studio was taken by a man of equally good artistic ideas, but who studied the taste of his public, with the result that a very lucrative and ever-increasing business was created.

It is quite a mistake to imagine that first-class technical work cannot be allied to artistic feeling; that is to say, that reasonably sharp general definition and full exposure are not permissible in a good picture. An "old master" effect where a strongly-lighted face stands out of Stygian darkness may be pleasing to a trained eye, but it is not acceptable to the mother who wants a remembrance of her absent son, or the girl who wishes for what is popularly called a speaking likeness, for presentation to one who knows her features well. If any proof of this were needed we have only to look at the photographs of deceased friends which are brought to be copied or enlarged, and we shall find that, almost without exception, they are clear, softly-lighted pictures, often amateur snapshots, although there may be many more pretentious portraits extant. It may not be known to all photographers that there are many people who prefer to have their children and themselves photographed at the seaside "on account of the clearer light there." London is, we know, sometimes murky, but in this age of electric lighting it is never impossible to take a clear photograph.

Let it not be supposed that we counsel a return to hard negatives and glossy prints, although these still find favour in some industrial districts. Modern printing methods will give all the delicacy of the old albumen and chloride papers, with the added advantages of variety of surface and tone.

There is, however, no need for the photographer to stifle his instinct for producing striking and even bizarre effects, but he should indulge it as an amateur, that is to say, for his own pleasure, and not try to persuade his clients to have what they do not really care for. If a business in this class of work can be created—and some have done it—well and good, but it is desirable to keep it as a side line until a demand arises.

The use of soft-focus lenses places a great power in the hands of the discriminating worker, but it is a power that is easily abused, and it is wise to use only those in which the degree of softness can be controlled without affecting the exposure, so that a slight softening for small heads or a greater one for large work can be obtained without departing from the usual methods.

A very great aid in producing technically good results exists in the panchromatic plate, which should be more extensively used than it is for sitters whose hair and complexion cannot be rendered successfully with an ordinary or even an orthochromatic emulsion. With it, and a suitable filter, which need not more than double the exposure, a negative needing little retouching can be obtained, and the risk of losing the likeness reduced to the minimum.

The inartistic photographer is likely to rely too much upon retouching to make good his deficiencies, and great restraint is necessary in this direction. Careful attention should be given to the lighting so that harsh shadows are avoided, attention should be paid to the contours so that as little knife-work as possible is needed.

To sum up, the wants of the great bulk of sitters are a good likeness, a technically perfect photograph, and all the artistic skill that the photographer can put into his work.

THE PICTORIAL IN COMMERCIAL ADVERTISEMENT PHOTOGRAPHS.

[A professional maker of advertisement photographs, Mr. J. Wallace Pondelicek, contributes an interesting account of his aims in this field to a recent issue of "American Photography." He represents a type of photograph supplier which may be said to have originated in the United States, namely, one who applies all the taste and feeling and technical skill which enter into pictorial work to the making of photographs for use as advertisements in the magazines. In this aim to draw favourable attention to goods by making appropriate photographs which also attract by their instrinsic beauty, he is distinguished from the photographic illustrator. Little work, such as his, is as yet produced for advertisers in this country, and thus in the development of advertising along pictorial lines, a large field of business, in which the photographer should share, remains chiefly in the hands of the draughtsman.—Eds. "B.J."]

Just a few years ago photography was considered more or less a mechanical commercial medium, a means to secure a record of given subjects. That was several years ago. However, to-day, thanks to the infinite pains and study of persistent workers, photography has made fast and inspiring advances, and has won its place among the arts.

The painter expresses his mood in colour—warm colours for the high-keyed sunny effects, cold colours for more sombre work. In photography one has just one colour to work with, and that is the so-called black, which in itself being a cold colour, is rather difficult to work with.

To portray the atmosphere of a bright sunny day, the sensation of feeling, the registration of human personality and character, photography is a most sympathetic medium, within its limits: a knowledge of chemistry, optics and the posing and expression of subjects, also lighting, must be had. I have seen many wonderful examples of photographic work, truly some essaying the recall of shimmering gray and blue canvases of Corot and others the brilliance of the Spanish painter Zuloaga, and many others that possessed all the vibration of sunlight and quality of colour, really wonderful when considering that they were done in monochrome.

When photography entered the field of advertising, the artist had only a subject pictured in monochrome to make a direct appeal to the public with, and when we take into consideration certain things about the public, we can easily appreciate the advantage the painter had over the camera man with his illustrations in colour.

In the first place, the public will not reads ads., if it can help it. You no doubt have noticed in magazines just when you are reading the most interesting part of a story at the bottom of the page you find the words, "Continued on page 97," and after ploughing through the magazine, you find on page 97 a large four-column advertisement and one column of story and so on, until you have read the story through. You have gone on reading single columns on ten different pages and have seen several dozen ads. whether you wanted to or not. Some of them you read and some you passed up. The commonplace ones, if the story was not thus distributed, you probably would never look at in the back pages of the magazines. You must make the public read the ads., hit them between the eyes with your ad. If you are to make the public read, your story must be told quickly, in pictures, headlines and brief summaries.

Advertising illustrations to be truly successful, must reflect and radiate the individuality of the product and producer, must inspire confidence, must have a human appeal, and must conform to the rules of artistic composition. The public does not know composition, but it does know an appealing striking picture, whereas an illustration not well handled is passed up as commonplace and ordinary.

Advertising and advertising illustrations are essentially salesmanship on paper. It is the breaking down of sales resistance. You must illustrate to create a buying desire, and favourable mental impression in the minds of your public. Flat, lifeless phrases, generalities that talk and say nothing, are no more effective than the halting mutterings of a young salesman afraid of himself.

As a rule, you will notice that an advertiser has a follow-up system of advertising, a sort of continued story. His ad. this month has a direct connection with his ad. next month. These campaigns, known as national, are planned a year in advance and the illustrations bear the same technique or treatment throughout the year, and if done successfully, you will be looking for the next month's ad., and after seeing several you will investigate the product, and nine times out of ten you will buy in preference to some other similar article you have never heard of. Photographic illustrations, like advertising copy, must be brief and striking. The public wants something different. You cannot go into too much detail when making an illustration. You must leave something to the imagination of your reader, new ideas, new styles, new treatment and technique, always a striving for the attraction of the public. The elimination of detail and the presentation of the essential idea is based on the principle that suggestion is more powerful in the mind than actuality.

The public is made up of people, not types. The illustrator will reach his public oftener and more broadly if he ceases to look for the difference between people and turns his attention to likenesses, and so when you illustrate, do not be afraid to aim high. Think of the public as a body of potential buyers whose mentalities rate above the average, then when you aim high, your illustration has an appeal. It not only portrays an article, but is educational and tells an impressive story.

It is extraordinary to what an extent "mood" and atmosphere are determining factors in the effectiveness of an advertisement. In connection with an article like underwear for women, a consideration presents itself that you do not have to contend with when illustrating other commodities, that is proper presentation. There are difficulties connected with underwear that are not encountered with other articles of women's dress. It is a great deal more intimate than corsets and stockings. General reference to corsets or stockings will pass in almost any stratum of polite society, but reference to the individual articles of women's underwear, except the use of the general term, is universally frowned upon, therefore the presentation of underwear must have the atmosphere of delicacy and refinement. The mood can be delightfully gay and dashing or quiet, calm and thoughtful, yet the same atmosphere of refinement must surround both. The appeal must be broad and universal so "Everywoman" can find something interesting in it. The selection of a proper model is very important, one with refined features, also posing, lighting and handling of plate, and last of all, a different idea from what already has been done, to arrest attention.

Advertisement of gramophone records is another story. Here we have music, which in itself suggests a hundred and one ways of presenting it attractively. In this instance, I have put the spirit of the dance, joy and nature's beauty. Development and treatment of these subjects were done in high key with one thing in mind, to keep the illustration in a sunny, joyful mood.

The campaign for a milk company (Carnation milk) was based upon photographs of real, live, every-day human beings. The idea behind was the human interest appeal. To give

cohesion and maximum quantity of pulling power, the advertisements were planned in a series under the headline of the Carnation Typical American Family. As a result, the various characters were sought, Grandpa, Grandma, Father, Mother, Auntie, Sister, Sonny and the Grocer, alternating their appearance in the advertisements either posed in group or individually with proper surroundings, the object being to make these faces familiar all over America, each a fine attractive type, the kind you would like to meet in real life, the advertisement appearing under headings showing various activities of the family relating to the purpose and use of Carnation milk.

Goodyear tyre advertisements are others which I have made. They tell the story of where Goodyear tyres are used, illustrations showing the All-Weather Tread on Fifth Avenue, the Palisades, Michigan Boulevard, the American deserts, the Apache Trail, Arizona, the Grand Canyon, the Rockies, and a hundred others taken all over the country, always showing some either historical or memorable part of the country in the picture with the Goodyear tyre and All-Weather Tread tyre impression in the foreground, this style of advertisement not only showing the uses of the tyre in various parts of the country, but acquainting the public with the beauties of our country.

The field for photographic advertising illustrations is unlimited. The examples mentioned are some of the campaigns I handle. I have made illustrations for almost every possible article, from still lifes of shoes, jewellery, potatoes, to the most elaborate set-ups using models, stage scenery, etc. It will probably interest the reader to know that every illustration I have made, I have used one of my many Pinkham and Smith semi-achromatic lenses. With a lens of this type you have every possible mood and feeling at command. You can create atmosphere that is impossible with a corrected lens. With proper handling you have at your command a lens you can almost talk to. I use an orthochromatic plate with or without filters, just as occasion may present itself. Very seldom do I find it necessary to use a panchromatic. For all of my outdoor work I use a K-2 and K-3 filter both at the same time. This enables me to use my lens at a wider opening, giving me fine colour values and more control on exposure, exposure being approximately $\frac{1}{2}$ second at $f/6.5$ on bright sunny days. The developer is the old standard pyro in tray, using about half the carbonate specified in formula and adding carbonate dependent upon the mood and atmosphere you are working for; more carbonate for high-keyed sunny effects and less for those of more sombre or softer quality.

A great deal could be written about advertising illustrations, but the summary would be good natural posing, attractive lighting, practical handling of lens and plate, forceful, brief, well-composed pictures, appealing to the human interest.

To make an illustration is one thing—to fit it into a story is another, to do both requires skill, creative ability and imagination. Whether an illustration is made to express vivid action or still life, in either case it must speak louder than words.

J. Wallace Pondelicek.

"Props" for Naturalist Photographers.—A representative of the "Daily Chronicle" has been having a talk with Mr. W. Clarkson about the making of property animals for pantomimes, and we quote the following note from a report of the interview: —Not all the works of the property masters are made for stage purposes. Life-size leopards, lions, tigers, ostriches and giraffes have been ordered by big game hunters and bioscope firms for use in the jungles. "We make them hollow to hold two men," said Mr. Clarkson, "and there is a hole in front of the breast for the camera, and two holes for rifles. The camera man inside the dummy tiger works in front, and he is guarded by the man behind inside, who controls the rifle triggers. A ring of burning material is put round the dummy animals when placed in the jungle, in order to stop the real animals from scenting the human beings inside them."

Photo-Mechanical Notes.

Multiple Negatives for Photo-Lithography.

In making up a printing plate for an offset machine, of small units, the necessary number can be obtained by repeated exposures on the sensitised plate; laying the negative each time upon register marks, corresponding with marks placed on the copy for the purpose, and shielding the extra surface of plate from light-action during each printing down.

This method answers well when the units are large and the multiple printing does not exceed eight, but when small labels, stamps, etc., where the completed print does not exceed 6 x 4 ins., are to be done, then a step and repeat machine is required, especially for fine colour work.

When the units are larger, multiple negatives may be built up of negatives made upon Transferotype paper, trimming to exact size, and transferring the requisite quantity to a large sheet of glass, giving a large negative made up of a number of smaller ones.

First of all, make from the original a negative the exact size of the unit, or label, required. From this negative, make a positive by contact, and from this positive make the requisite quantity of small negatives or prints upon Transferotype paper to fill up the printing plate.

The copy negative is best made by the wet collodion process, the contact positive upon a process dry plate, developed with the following hydroquinone developer:—

No. 1.—Hydroquinone	.....	180 grs.
Potass. metabisulphite	.....	$\frac{1}{2}$ oz.
Citric acid	.....	60 grs
Potass. bromide	.....	60 grs.
Water	.....	20 ozs.
No. 2.—Caustic soda	.....	180 grs.
Water	.....	20 ozs.

For use, take equal parts of No. 1 and No. 2. Fix in:—

Hypo	.....	6 ozs.
Water	.....	20 ozs.

This developer is also used for developing the negative prints made upon the Transferotype paper.

The transparent positive may be fixed in an acid hypo bath, but the Transferotype negative prints must be fixed in plain and freshly-mixed hyposulphite of soda.

Care must be taken all through the process that the lines are clear glass in the case of the negatives, and in the positive that the lines are quite dense, and the other parts quite free from veil.

The negative prints made under the positive must have all the characteristics of a good line negative, viz., the lines quite white, and the ground perfectly black. Using a contrasty Transferotype paper, giving it the proper exposure, and developing with the formula given above there will be no difficulty on this point.

The negative prints when dry should be trimmed exactly to size, allowing in this for a slight expansion when again wetted.

This fact of expansion when wet, inherent to all paper prints, suggests that unless some means are adopted to prevent any expansion, the use of paper for making negatives for colour work is not practicable. This is quite true, but for ordinary black and white labels, etc., this expansion is quite negligible.

Fortunately the trouble can be obviated quite easily by soaking the paper in clean water until limp, then squeegeeing down upon a sheet of glass that has been previously thoroughly cleaned and polished with French chalk, or what is perhaps better, first smeared with vaseline, polished off, then dusted with French chalk and polished until this is quite polished off. Once this is done the plate will be usable quite a dozen times without re-polishing; even then only a French chalk polish is necessary.

The sensitive Transferotype paper, wetted till limp, is then squeegeed into contact with the glass, and dried (in the dark-room, of course, and also the soaking and mounting on the glass must be dark-room operations). When dry, the paper is stripped off the plate and cut up into sizes for printing upon. Paper dried as above is at its full stretch as regards both dimensions, and cannot expand any more either way, so that small negatives made upon such stretched paper may be relied upon to give good register.

The prints being made and trimmed to size are next wetted until quite limp. They are then assembled upon a sheet of British plate-glass which has been previously coated with :—

Gelatine	2 ozs.
Water	20 ozs.
Potass. bichromate (saturated solution) ...	1 dr.

Filter before use, and coat whilst warm. The glass plate is scrubbed, and well washed, and then coated with the above solution, drained, and dried in full daylight.

When the prints are assembled (having plenty of water on the plate, which is best laid flat), place a sheet of rubber cloth all over the prints and squeegee down lightly. Remove the rubber cloth, and carefully examine the prints, and by the aid of set square, T square, and straight edge, coax by slight touches all the prints into exact positions. Again cover with rubber cloth, and squeegee as hard as possible. Keeping the rubber cloth in position, erect the glass plate, and finally examine the negatives. If any are displaced, the remedy is easy; they are still movable sideways, may be removed bodily, re-wetted and replaced. After the final squeegee, place a sheet of glass upon the rubber cloth and leave under that pressure for an hour. Next immerse the plate in water at a temperature of about 110 deg. F., and in a few minutes the paper backings may be lifted off. Now gently lave the water over the negatives so as to get rid of superfluous gelatine, wash for a few minutes in cold water, drain and put away to dry. After draining 10 to 15 minutes, examine the films, and if there are any tears, remove them by dabbing gently with a damp chamois or with fluffless blotting paper.

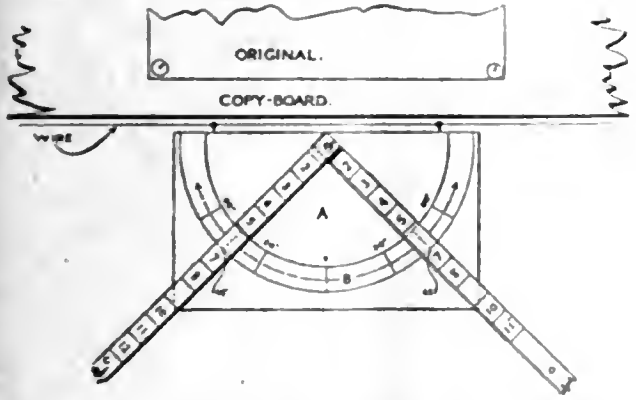
For poster work, enlargements can be made any size up to 60 x 40 upon this paper, and the print transferred to a glass plate for printing down upon metal.

The plates upon which these prints have been transferred can be made available for other negatives by soaking in an acid pickle, then washed and re-coated with the bichromated gelatine. W. T. Wilkinson.

Exposure in Systematic Process Negative Making.

An important item when determining the exposure in systematic negative making is the distance and angle of the lamps from the original. There are two optical laws to be considered when calculating the different exposures with varying light distances and angles, 1st light varies inversely as the square of the distance, and 2nd intensity of illumination varies directly as the cosine of the angle of incidence of the light to the surface being illuminated. These are not always understood and appreciated, but they play an important part in systematic work.

The writers have devised a simple apparatus for determining the angle and the distance of the lamps from the copy, and which is



in use at the L.C.C. School of Photo-Engraving. The sketch illustrates this apparatus. The base-board A has a radial scale B marked out to 30 deg., 45 deg., and 60 deg., the arms C and D are marked out in inches, and swing on a pivot E round B.

For convenience the side where the arms meet can be hinged to the copy-board in such a way that the point E may be brought to the middle of the copy, the device hanging down when not in use, the illustration shows the method adopted for the purpose mentioned. To set the angle, and to fix the distance of the lamps from the original, the apparatus is raised to a horizontal position, and E brought to the middle of the original when the distance and angle of the lamps can be set. The lesser or additional exposure for a known exposure when varying light-angle and distance is shown approximately in the table, or can be calculated by the following formula :—

$$\text{New exposure} = \left(\frac{\text{new distance}}{\text{old distance}}\right)^2 \times \text{exposure at old distance} \div \text{by cosine of angle of incidence.}$$

The following is the manner of using the table, which is calculated for use with two enclosed arc lamps on a 200-volt circuit, each lamp taking 10 amps. An exposure is 2 min. at 18 ins., and it is required to know the increase of exposure when the lamp distance is extended to 24 ins., the lamp angle being 60 deg. Opposite new distance of lamps look for factor under 60 deg., i.e., 2.85, multiply known exposure by this factor, $2 \times 2.85 = 5.7$ the required new exposure. If the distance is to be reduced the known exposure is divided by the factor.

Lamp distance.	30°	45°	60°
18 in.	1.00	1.23	1.78
20 „	1.23	1.52	2.15
22 „	1.49	1.84	2.60
24 „	1.78	2.20	3.10
26 „	2.09	2.60	3.64
28 „	2.42	2.87	4.20
30 „	2.79	3.42	4.66

If distance be 24 in. at 30 deg., and it is required to know increased exposure for 28 in. at 60 deg., take reading for 24 in. under 30 deg. = 1.78, and reading for 28 in. under 60 deg. = 4.2. Subtract 1.78 from 4.2 = 2.32, which is the factor for multiplying known exposure at 24 in. to obtain approximate exposure for 28 in. at 60 deg.—W. J. Smith and E. L. Turner.

Exhibitions.

THE "OLD MASTERS" OF PHOTOGRAPHY AT THE R.P.S.

Photographic old masters who may claim to be "primitives" are very few. The Royal Photographic Society should know, if anyone should, all there is to know about the artistic history of their subject: but their efforts have resulted in a collection that is made up chiefly of works by D. O. Hill, half-a-dozen by Mrs. Cameron, and seven by Rejlander. There must be other old masters, however. I once saw a collection of remarkable architectural works by a contemporary of Hill. His name I forget, but it would be a worthy quest to rescue such works from the obscurity of the distancing past.

The collection of Hill's work necessarily includes many duplicates, because collectors who lend prints are disposed to stipulate that their collection shall not be broken up. This prevents selection of examples, with the consequence that the visitor sees some of the portraits two or three times over. Perhaps this is no disadvantage. Comparison between specimens is made easier by this condition. There is certainly something perennially fresh in Hill's work, and I am disposed to think that its undying charm lies in the simple naturalism of its presentment. There is, of course, an attraction to some in the old-world style of its sitters; but that alone would not make Hill famous. Indeed, there are not a few portraits here that would certainly suffer the scoffs of the modern young person of either sex, from a point of view of subject-matter. But the worst of the "guys," the most "soppy" of the divines have the strength and dignity of simple truth. The prints are straight records, unaided by the artistic after-treatment which would be accorded them were they the products of to-day; and it is this obviousness of frank naturalism that takes us back to their time, placing us, in mind, beside the sitter. As a result we sympathise. We feel with the old beetle-browed ones; we understand the psychology of the demure, smooth-haired maidens.

All these prints have quality, sometimes of a rare beauty. Two

little landscapes, or rather town scenes, are rich in it. How far this quality is an accidental and happy result of the technical processes and how far it may have been schemed for is hard to determine. A statement was recently made that Hill's part stopped short of exposure and print production. That, at any rate, would still account for the vigorous and beautiful effects of frank light and shade, to which much of the quality is due. That the posing and lighting are the work of a painter is obvious almost everywhere, because they are at once conventional and beautiful. Some of the groups of figures are most ingeniously arranged.

There is nothing of this sort about Mrs. Cameron's work, except in the case of the Herchel, which is certainly an inspiration. The difference between her work and Hill's is that Hill's, if produced to-day, would command respect, whilst the other would be negligible.

Rejlander seems also to be in enjoyment of an over-estimated reputation. It is good work, but it does not reach across the years as Hill's does.

To hang with these things of a past day the admirable prints of Mr. T. Elliott, of Cape Town, is a good plan. The shock is rather severe, but it wakes one up to the fact that what was the source of beauty in early photography is still potent. Actual sunshine, which revealed all Hill's modelling, gives Mr. Elliott his theme. The white walls of somewhat fantastic buildings, upon which the parallel rays catch every inequality add their shadows as a contribution to the quality of the whole. One seldom sees buildings, skies and verdure in such perfect accord in camera pictures. In one or two cases tone values, and colour values, too, seem to be as dead true as it is possible to get them. The result is the charm of natural beauty.

F. C. TILNEY.

Patent News.

Process patents—applications and specifications—are treated in "Photo-Mechanical Notes."

Applications, November 14 to 19.

FINDERS.—No. 30,606. Finders for photographic apparatus. G. Arndt.

ENLARGING APPARATUS.—No. 30,454. Photographic enlarging or projecting apparatus. D. O. Bremner.

PHOTOGRAPHY.—No. 30,385. Photography. W. Carroll.

CAMERAS.—No. 30,760. Cameras. Crown Cork and Seal Co.

MIRRORS.—No. 30,394. Mirrors for projector lamps. F. Krupp Akt.-Ges.

MIRRORS.—No. 30,432. Mirrors for projector lamps. F. Krupp Akt.-Ges.

LAMPS.—No. 30,433. Projector lamps. F. Krupp Akt.-Ges.

ARC LAMPS.—No. 30,434. Arc lamps for projection. F. Krupp Akt.-Ges.

CINEMATOGRAPHY.—No. 30,431. Fire-protecting devices in cinematographic projecting appartus. F. Krupp Akt.-Ges.

COMPLETE SPECIFICATIONS ACCEPTED.

These specifications are obtainable, price 1/- each, post free, from the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C.

The date in brackets is that of application in this country; or abroad, in the case of patents granted under the International Convention.

COLOUR PHOTOGRAPHY.—No. 166,028 (June 4, 1920). The invention consists in a process for the production of photographic negatives for colour printing or other purposes, consisting in dispersing a source of light into the form of a spectrum and photographing the object successively upon a plurality of negatives, the object being illuminated for each negative by a selected portion of the spectrum, and the selected portions of the spectrum being mutually exclusive.—Adrian Bernard Klein, 32, The Pryors, East Heath Road, Hampstead, London, N.W.3. (Further details of the specification are given on another page in the "Colour Photography" Supplement).

COLOUR CINEMATOGRAPHY.—No. 147,767 (September 10, 1918). The photographs are taken a pair at a time by a pair of lenses having their axes parallel. Two glass plates are arranged parallel to each other, each in front of one of the lenses, the first plate being a transparent and the second an opaque reflector. Successive pairs of pictures are taken alternately through two pairs of colour filters.—Giovanni Casieri, 17, Via Fibonacci, Pisa, Italy. (Further details of the specification are given on another page in the "Colour Photography" Supplement.)

PHOTO-SCULPTURE.—No. 170,685 (July 30, 1920). The invention relates to improvements in the production or reproduction of a copy of a three-dimensional figure in relief or in intaglio, by which a graphic record of a three-dimensional figure is obtained on a plane surface and is used in the production of a pattern, which pattern is then employed to actuate and control the movements of a graving tool in a carving machine. The graving tool cuts the block of material on which the copy is to be made, and the movements of which are co-ordinated with those of the graving tool.

The invention relates to the known method of producing the pattern by projecting a design on to the figure, photographing the figure with the projected design and from the negative preparing a pattern to be employed in a carving machine.

If a transparency, say a lantern plate, bearing a design be placed in an optical projector normal to the optical axis of the lens and the design be projected, as ordinarily, on to a

Fig. 3.

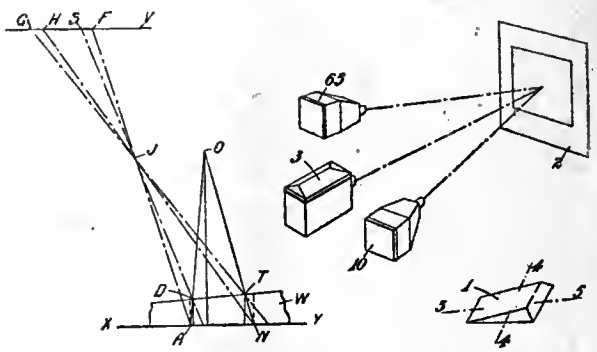


Fig. 1.

Fig. 2.

screen X Y (fig. 1) normal to the axis of projection, an undistorted image of the design, differing in scale but in no other respect geometrically, will be cast on the screen. If the projected image of the design be photographed in a camera on a sensitive plate V parallel to the screen X Y through a lens of sufficient covering power and having its optical axis parallel to that of the projector lens, a photograph of the projected image will be obtained, which is changed in scale only. If a three-dimensional figure W (shown in fig. 1 as an irregularly shaped figure and in horizontal section) be substituted for, or placed against, the screen X Y and the design be projected thereon, the projected image of the design will be distorted or displaced wholly or in part, the displacement of any point in the design being a function of, and substantially proportional to, the distance by which the point it covers on the figure W is removed from the

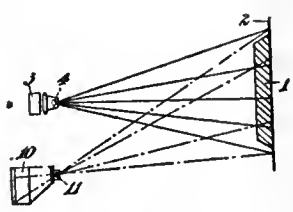

Fig. 4.

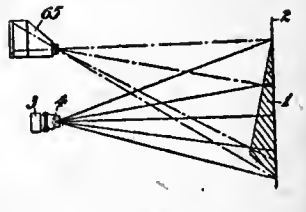

Fig. 5.

point it would have covered on the screen X Y. If the camera be placed with the incident nodal point J of its lens in line with the incident nodal point O of the projector lens adjacent the figure, and the line joining these points parallel with the screen X Y, all points of the projected image that are displaced will be recorded on the plate V as displaced in a direction parallel to one another and to the line joining the nodal points J O.

In order that the principles of the invention may be clearly understood, let only two points of the design on may be clearly understood, let only two points of the design on the transparency be considered, and let A and N indicate the positions the projected images of these points would occupy on

the screen. A photograph of the projected image points A and N will be registered on the plate V at the points F and H respectively. When the figure W is placed against the screen X Y the images of the two points of the design will be projected on the figure W at D and T respectively, and photographs of the projected and displaced image points D T will be recorded on the sensitive plate V at S and G respectively. The distances A D and N T are measures along the rays O T N, O D A of the actual displacement of the image points from the screen and the distances S F and G H are measures of the apparent displacement of such points as registered on the plate V. The distance S F is a function of the distance A D and the distance G H, a function of the distance N T, and G H bears to N T substantially the same ratio as S F bears to A D. All points on the figure W at an exactly equal distance from the screen undergo an equal apparent displacement—that is, the ratio of apparent displacement for such points is a constant.

The foregoing explanation is true in all cases. In those cases in which the depth of the figure increases relatively to the distance between the projector lens and screen, the departure of the resulting bas-relief from true form will become greater and greater. It follows from what has been said that if the image of a line be thrown by the projector on the figure W and the image be photographed, the position on the sensitive plate the undisplaced image of the line would occupy is ascertainable and a graphic record is obtained, on which is defined a line every point in which is distant from an ascertainable point on the plate according to a ratio that is substantially a constant for every point on the surface of the figure and its corresponding point on the screen, and the displacement on the plate is in a direction parallel with the line joining the incident nodal points of the projector and camera lenses.

The foregoing relationships are involved in the production of a graphic record on a plane surface of a three-dimensional figure, and the method employed consists in projecting a design, preferably of lineal form, on to the figure, and it may be on to a plane

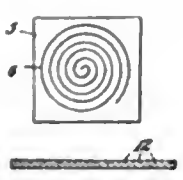

Fig. 6.

Fig. 8.

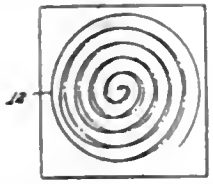

Fig. 7.

surface either before, simultaneously with, or after the projection of the design on to the figure, photographing the figure and the projected image of the design, and from the negative preparing a pattern of the distorted or displaced design to control the movements of a graving tool of a carving machine. The characteristic feature of the method is that the camera is placed with the incident nodal point of its lens in the nodal plane of the projector lens adjacent the figure. The pattern may be an engraving or photograph when optical control of the graving tool is employed, and in such case the control is effected by causing the cross hairs of a microscope mounted on the graving tool carrier to follow the distorted line of the design. When mechanical control is employed the pattern is a grooved plate with which a member on the graving tool carrier engages. The term "nodal plane" means a plane normal to the optical axis of the lens and passing through the nodal point.

Apparatus for carrying out the method set forth in the preceding paragraph comprises an optical projector having a well-corrected lens, a transparency to be placed in the projector and having the design thereon, a plane surface on which the design is first projected for focussing and which is removable in whole or in part, and a camera also having a well-corrected lens and positioned with the incident nodal point of its lens in the nodal plane of the projector lens adjacent the plane surface.

The design is preferably lineal, but may be otherwise, so long as it is such that the pattern, when placed in the carving machine, can have imparted to it a movement which is identical with the undistorted form of the design. For example, if the design be an arithmetical spiral, and such a design is preferred, the pattern is moved in the carving machine in suchwise that every point thereof moves in a spiral path. A design consisting of a grid constituted of equally spaced and parallel straight lines is suitable, but in the following description, a design consisting of an arithmetical spiral is assumed to be employed, though the invention is not limited to such a design.

Fig 2 is a perspective view of a three-dimensional figure, of which a copy in relief is to be produced.

Fig. 3 is a perspective view of the units employed assembled in proper relationship for the obtaining of a photograph from which a pattern is to be made.

Figs. 4 and 5 are views at right angles, with the object shown in fig. 2 placed against the screen.

Fig. 6 is a view of a transparency, such as a lantern plate, with the design of an arithmetical spiral thereon.

Fig. 7 is a view of the pattern used in the graving machine for producing a copy in relief of the object shown in fig. 2, and

Fig 8 is a sectional view of fig. 7.

The object 1 (fig. 2) is placed against the screen 2, and is supported in any convenient manner. The optical projector 3 is placed in position with the optical axis of its lens 4 normal to the screen 2. A transparency 5 (fig. 6) having defined thereon an arithmetical spiral 6 is placed in the usual manner in the projector 3 so that the design may be thrown on to the object 1. It is desirable that the field illuminated by the projector should be so large that a portion of the image of the design is thrown on to the screen 2 itself, as in such case assistance is rendered to the adjustment of the pattern in the carving machine. The image of the design being projected on the object, and preferably on a portion of the screen, a photograph is taken of the image as it appears on the object and screen by a camera 10 located so that the nodal point of its lens 11 is in the nodal plane of the projector lens 4. It is preferable, though not essential, that the optical axis of the camera lens be parallel with that of the projector lens. In many cases it is preferable to point the optical axis of the camera lens at about the centre of the figure to be photographed; when this is done the resulting negative must be placed in an enlarging lantern and a corrected copy obtained by tilting the enlarging screen in manner well understood. A photograph having been taken and the sensitive plate subjected to the usual photographic developing operations, a pattern is made from the negative. The pattern is preferably made by line photo-engraving, though other processes to this end may be employed. When the pattern is made by line photo-engraving, the displaced or distorted spiral is defined by means of a groove 12. Figs. 7 and 8 show a pattern, on which is defined, by means of a groove 12, the displaced and distorted spiral.

The method of producing or reproducing a copy of a three-dimensional figure from a pattern prepared from a graphic record on a plane surface and which pattern is also all in one plane, consists in imparting movement to the pattern identical with the undistorted shape of the design, utilising the movement of the pattern to import rectilineal movement to a graving tool and in a plane parallel with that of the pattern, and imparting movement to the material to be cut or carved identical with the undistorted form of the design, for example, in the case of a spiral design, the movement would be compound, and comprises a rotary movement on an axis parallel with the plane of movement of the graving tool and a rectilineal movement at right angles to its rotational movement. The axis of rotation of the carrier is coincident with the graving tool at the time when the pattern is at the centre point of its spiral movement.

The specification also describes the mechanical details of the carving machine.—Howard Maurice Edmunds, Moulsecombe Place, Brighton.

The following complete specifications are open to public inspection before acceptance:—

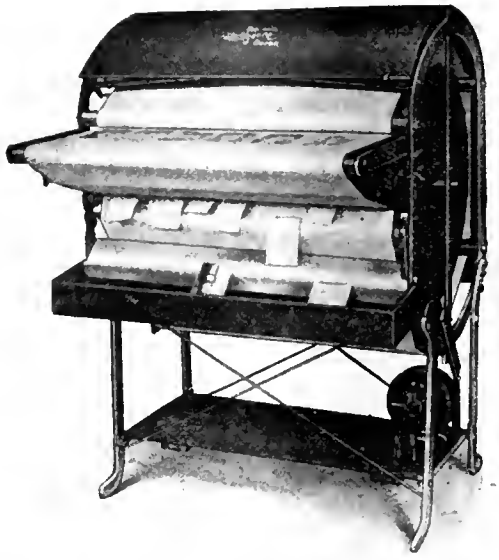
Cinematography.—No. 171,373. Machine for treating photographic moving picture films. Sen-Jacq Film Print Co.

The Most Popular of Hobbies. — Our contemporary, "Hobbies," deals with nearly every kind of hobby under the sun, though it is run mainly in the interests of fretworkers. A few weeks ago its editor asked his readers to send a postcard—there was, in fact, a competition with prizes—saying which were their favourite "pages" in the paper, but omitting fretwork, which is the weekly's mainstay. The result of the voting, announced this week, is (1) Photography, (2) Toymaking, (3) Stamp Collecting, (4) Carpentry. "Hobbies," it may be remarked, has run a photographic page weekly for about twenty-five years, and we are pleased to learn of its popularity. For the past sixteen years the page has been written, and is still being written, by Mr. P. R. Salmon.

New Apparatus.

The Hodgson Rapid Print Dryer. Made by the Hodgson Manufacturing Co., 2, Gerrard Place, Shaftesbury Avenue, London, W.1.

Of late years the rotary type of machine for drying prints by artificial heat has come largely into use and a number of patterns of this apparatus have come upon the market, all, so far as we know, of American make. A machine for this purpose of British manufacture is, therefore, of special interest, and particularly so when it can be emphatically said that it is of excellent design and workmanship. The apparatus, for which Messrs. Sichel and Samuelson, 52, Bunhill Row, London, E.C.1, are agents, is the design of Mr. Frank Hodgson, a professional maker of prints and enlargements, by whom the machine has been developed for his own requirements in handling large numbers of prints. As shown in the photograph, the apparatus is essentially of



the familiar type in which endless bands of fabric are led round an internally heated metal drum. The prints are carried between folds of the fabric, and during the passage of these latter round the heated drum, which occupies four minutes, are deprived of their adhering moisture. At a demonstration we saw prints taken straight from the wash water, dried in this manner by passage through the machine.

The apparatus is strongly made of a wrought-iron framework and has a steel gas-heated drum. The canvas bands can be easily removed for washing, simply by unscrewing four screws. The machine occupies a floor space of 34 x 26 inches, and is 4 ft. in height, so that it will be seen that it takes up comparatively little space in a photographer's establishment. It may be obtained for operation by hand at the price of £26 10s., but the preferable model is that fitted with electrical drive of the drum at the price of £37 10s. The motor supplied for this purpose is for continuous current. If alternating current has to be used an additional charge of £2 10s. has to be made. At the cost of a further £2 10s. the apparatus can be supplied with electrical instead of gas heating of the drum. As will be seen from the photograph, the prints are very readily fed in by laying them face up on a horizontal portion of the rotating web. After drying they are delivered on the same side of the machine and fall into a trough arranged to receive them.

There can be no doubt of the practical advantages of drying in this way. Prints are protected from dust during drying and are obtained with a very slight amount of curl. As delivered from the machine, they are in the best condition for insertion in folders without further mounting. For dry-mounting, we think it is to be recommended that they should be allowed to remain in a warm and dry place for some short time in order to become absolutely bone dry. Both for the output of a studio and for the business of developing and printing from amatenrs' negatives the Hodgson machine is a most efficient and valuable piece of equipment.

The apparatus is obtainable either from the makers or from Messrs. Sichel and Samuelson, and may be seen in working at the premises of both.

New Books.

The Great White South. By Herbert G. Ponting. London: Duckworth and Co. 30s. net.

In his cinematograph lectures on the Scott Antarctic Expedition, Mr. Ponting, by the superlative quality of his photographic and cinematographic work, brought the South Polar regions on to the lecture platform. In this book he has brought them to the fireside. It is not essentially the story of Scott's heroic journey to the South Pole, which has been told in the volume, "Scott's Last Expedition," in which chief use has been made of Captain Scott's journals and the records of his colleagues. But it is a profuse account, by an observer, of the main incidents of the expedition and of the geography and natural history of the desolate Antarctic regions. "Great God," wrote Scott in his journal, "this is an awful place and terrible enough for us to have laboured to it without the reward of priority." That was an entry in his diary on the day after reaching the Pole and discovering there the tent of the five Norwegians who had reached it a month before. Mr. Ponting's narrative, while it does justice to the extraordinary beauty of some aspects of the Antarctic scenery and to the interest of the animal life in those regions, does not neglect to underline the terrific sufferings which the explorers had to undergo, sufferings which culminated in the tragic death of Scott and his companions on their return journey 11 miles from a depot where they could have got food and warmth.

But the book will be studied with keen enjoyment for its most complete account of the life of the expedition and for its very numerous illustrations. There are nearly 200 of these, with few exceptions from Mr. Ponting's photographs, which are the most eloquent tribute to his artistic and technical skill as a photographer under outdoor conditions such as no other man has been called upon to endure. Quite apart from the absorbing interest of the story which the photographs tell, the book is to be signalised as the most important proof of the immense value of photography in exploration which has hitherto been forthcoming. From this standpoint, photographers especially will congratulate Mr. Ponting upon his authorship and upon the completion of so notable a work in the literature of exploration.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

MONDAY, DECEMBER 5.

Accrington C.C. Exhibition of Folio of Leicester Phot. Soc.
Birmingham Photographic Art Club. "Highways and Byways of Shakespeare Land." W. A. Clark.
Bowes Park and District P.S. Lecturette Competition.
Bradford Phot. Soc. "The Flora and Fauna of the Scilly Isles." G. A. Booth.
Dewsbury Phot. Soc. "A Chat on Pictorial Landscape." H. G. Grainger.
Forest Hill and Sydenham P.S. Print and Lantern Slide Competition.
Glasgow & W. of Scot. Amateur P.A. "Photo-micrography." D. B. Duncanson.
Kidderminster and Dist. P.S. "Harvington Hall." Dr. E. E. B. Landon.
Leeds C.C. "Photography on Tour." Fred. J. Seaman.
Rochdale Amateur Phot. Soc. "Paget Colour Photography." A. Benson Ray.
Southampton Camera Club. "How a Reflex Camera is Made." W. Butcher & Sons.
South London P.S. "Switzerland." Capt. J. H. Jennings.
Wallasey Amateur P.S. "Collected Notes on Pictorial Composition." John R. Charlton.
Walthamstow & Dist. P.S. "A Review of the Exhibition." Bertram Cox.

TUESDAY, DECEMBER 6.

R.P.S. "A New Mode of Producing Sculptures by the Aid of Photography." Howard M. Edmonds.
Belfast C.P.A. Camera Club. "Multiple Mounting." W. J. Rankin.
Birmingham P.S. "One Man" Collection, by Mr. F. Judge.
Cambridge Photographic Club. "Contact Printing and Enlarging on Vitegas." Demonstration by Mr. Brewster, of Messrs. Kosmos Photographics, Ltd.

Wimbledon & Dist. C.C. "Simple Picture Making." R. H. Lawton.

FRIDAY, DECEMBER 9.

Wombwell and Dist. P.S. Beginners' Night.

ROYAL PHOTOGRAPHIC SOCIETY.

Meeting held Tuesday, November 29, the president, Dr G. H. Hedman, in the chair.

Mr. Colin M. Williamson, in reading a paper on "Photography and Mechanics; Facts and Possibilities," dealt with photographic apparatus which came within the province of the mechanician, viz., that for cinematography and aerial photography. In referring to cinematograph apparatus, he dealt with cameras of distinctive design, and particularly with those having a self-contained motor for moving the film. The Aeroscope, air-driven, as now manufactured, was, he said, a very satisfactory instrument, and was being used on the Shackleton expedition. He also described the Sept camera, which took film for an 18-seconds picture on the screen. Though the time was short, a great deal could be got into a film of this length, and the camera was used in part for taking pictures for the "Pathé Gazette." It was driven by clockwork, and Mr. Williamson thought that spring motors could be made for actuating much longer lengths of film than at present if clockwork makers set themselves to reduce weight. The lecturer dealt also with high-speed cinematographs, and described some of the models which had been produced.

Turning to aerial cameras, he dwelt upon the alternatives of films and plates, and showed the construction of the automatic air-propelled camera designed by him for the Royal Air Force and used in the East in 1916. He explained the latest model of camera made to the requirements of the R.A.C., electrically operated, and giving records on each plate of altitude, compass bearings, and other required readings.

Mr. Williamson ventured on a forecast of the aerial military photography of the future from an aeroplane without human pilot, in which all the operations of manœuvre, as well as those of the photographic equipment, would be controlled by wireless from a distant land station. He thought that there was a reasonable probability of such a system being realised.

The automatic development of cinematograph film was also illustrated by photographs of a plant in which film continuously passed through developing, fixing, toning, and washing solutions contained in long, vertical tubes, and thence through drying tubes to the re-winders. He said it was remarkable that in America, where the film industry had made such strides, development continued to be chiefly done by the less efficient manual handling in tanks.

A brisk discussion followed in which Messrs. E. W. Mellor, A. C. Banfield, Jennings, King, Pereira, and Colin Bennett took part, and, on the proposition of the chairman, a hearty vote of thanks was accorded to the lecturer.

CROYDON CAMERA CLUB.

Quite a little drama was enacted prior to last week's meeting, which Mr. Sellors was booked to fill with one of his infallible systems which occasionally go wrong. Unfortunately he fell victim to a chill, but bethought himself of an old friend of the club—Mr. Luboshez, who agreed to lecture with the greatest pleasure, provided this country held him on the date.

Shortly prior to such date the gifted, ever resourceful and slightly erratic Kodak genius crosses a corridor and invades the Kingsway sanctum of Mr. T. Bell, the advertisement manager, and explains he is due at Croydon and in Sweden simultaneously, and is obliged to favour the latter for business reasons. Would Mr. Bell kindly undertake Croydon in his place? "You go to blazes!" says Mr. Bell. Later, Mr. Wratten, located above, receives the same visitor with the same tale, a bag is banged down on the table, and an intimation given that a complete lecture is within, all piping hot for Croydon on the morrow, and exit the artist speedily, looking Mr. Bell up in transit to the street to say things have been nicely arranged. "Accept my blessing, and close the door after you," says the relieved Mr. Bell. Meanwhile, the occupant of the room above has opened the bag and discovered the MS. to be pre-war and written in German, and, much perturbed, he descends to implore the help of Mr. Bell. Cordial agreement as to the character and probable future of the absent one assuages their feelings, but does not save the situation, which, however, is eventually met.

A large and extremely interesting collection of splendid prints from the foremost studios of America and the Continent was the outcome, with Mr. Wratten as introducer to the lecturer, Mr. Bell. The former contented himself with a recital of the foregoing drama, with a forcible character sketch of the villain of the piece.

Mr. Bell added his quota, defining Mr. Luboshez as a remarkable being who was never at any one time at any one spot, but always approaching or receding from it. For years, he said, he had been collecting examples of the best workers abroad, and the prints on the walls had never before been publicly shown. He then passed on to an instructive and critical review of the exhibits, pointing out how the various photographers had developed on different lines following their varying ideals of the beautiful. For instance, one emphasised "tone," another "light and shade," whilst many found their greatest pleasure in the rendering of "beauty of line." It was fortunate for Art that this was so, for it would be but a poor thing if all were possessed of the same ideal. Personally, he regarded "tone" as paramount, and nothing could altogether atone for its absence.

A discussion followed the lecture, in which many took part. The president, Mr. John Keane, only expressed the opinion of all when, in proposing a vote of thanks, he said that the evening had been of outstanding interest, and would long be remembered. Thanks were also due to the "Elusive Pimpernel of Photography" for indirectly being the cause of it.

PROFESSIONAL PHOTOGRAPHERS' ASSOCIATION.

A meeting of the Council was held at 35, Russell Square, W.C., on Friday, November 11, 1921. Present: Messrs. Adams, Basil, Chase, Corbett, Ellis, Gray, Haines, Hana, Lambert, St. George, Speaight, Spink, Wakefield, Swan Watson (president), Wedlake, and Wheeler, and Lang Sims (secretary). Apologies for absence were read from Messrs. Frank Brown, Chapman, Dickinson, Illingworth, Read, and Turner.

Arising out of the minutes, Mr. Speaight mentioned that a copy of the rules of the Great Western Railway had been procured, and this distinctly stated that cameras or photographic apparatus up

to 60 or 80 lbs. could be carried by the passenger without any extra charge.

Mr. Corbett reported that he had interviewed the appropriate authority of the London County Council with regard to the storage of celluloid films, and had been informed that the Home Office was framing new legislation on the subject. Mr. Corbe't promised to take further steps in the matter, and report progress.

Certain members brought forward forms of indenture and particulars as to apprenticeship, as promised at the last meeting, and others promised to send forms to the secretary. The secretary was requested to look through the forms and the particulars generally, and to report on them at the next meeting.

Mr. Speaight (hon. treasurer) reported that, at the request of the Finance Committee, he had sent a personal and registered letter to a number of members who were two years and more in arrear with their subscriptions, and had asked for payment by that evening (the 11th). The result was that 24 had paid up, there had been 24 resignations, and eight letters had been returned with the intimation that the addressee was not known.

It was agreed that at the next Council meeting the list of all the defaulters should be read and their names struck off.

Mr. Hana thought that the Finance Committee should bear in mind the advantage of nominal strength, and that every possible consideration should be given to those who requested time to pay.

Mr. Speaight said that this was the policy of the Finance Committee.

The secretary read the report of the combined Congress, Finance, and Exhibition Committees, with the recommendation "That as the year 1922 would be the 21st anniversary of the foundation of the Association, a special effort be made to make the forthcoming Congress and Exhibition an advance upon all previous ones, and that new features of up-to-date interest to the profession be introduced."

Various schemes were put forward, and, after a lengthy discussion, further consideration was deferred until the next Council meeting.

It was agreed that the special general meeting, to be called to obtain further powers to make the Association a limited liability company, should be called for the date of the next Council meeting, December 9, at 6.30 p.m. The secretary raised the question of whether he was to send the notice of the meeting to those members, already referred to, whose subscriptions were two years and more in arrear, and who had not replied to the personal letter addressed to them. It was decided that no notice should be sent in such cases.

The solicitor attended in order to secure the signatures of members for the registration documents. He also said that the Companies' Registrar took exception to one of the object clauses, which ran: "To promote and carry on schemes for the insurance of professional photographers." An acceptable form was, "To procure from insurance companies advantageous terms for the members," and this was approved.

The solicitor raised the question of a registered office, and suggested that it might be the office of the auditors. The firm of Norton Slade and Co., of 9, Old Jewry Chambers, had been suggested, and that they should be appointed until the next annual general meeting. He thought that this firm would be willing to allow their offices to be used for this purpose.

On a proposition from the chair, it was agreed unanimously that Messrs. Norton Slade and Co. be appointed auditors until the next annual general meeting, at a fee of £10 10s.

The chairman said that the term of office for which Mr. Lang Sims was appointed came to an end on December 31, and it was necessary to decide what should be done during the first months of next year.

Mr. Haines proposed, and Mr. Wakefield seconded, that, in view of the expiration of Mr. Lang Sims' year of office as secretary, he be asked to continue in that office until the general meeting of the registered Association in April, 1922.

This was agreed to unanimously.

Mr. Lang Sims said he would do as the Council wished.

The secretary reported a number of new members from Nigeria, obtained through the medium of "Houghtons' Professional Bulletin." It was agreed that they be accepted.

A letter was read from the Hewittic Electrical Co. suggesting that the Council should set up a committee to test various systems of artificial light, with a view to fixing eventually on a comparative standard lighting. After Mr. Adams and others had spoken on the subject, Mr. St. George formally proposed that a committee be appointed to consider this matter, and this was agreed to unanimously, and the following were appointed:—Messrs. Marcus Adams (convener), Angus Basil, Gordon Chase, Alexander Corbett, George Hana, Herbert Lambert, R. N. Speaight, and Wakefield, with power to add to their number.

The secretary read a letter from an ex-service man who held a Ministry of Labour certificate and desired training for photography. It was decided to write to him, pointing out that no adequate training in photography could be given in the time stipulated.

Mr. Speaight proposed a vote of thanks to the president for his attendance. Mr. Swan Watson had travelled all the previous night from Scotland, and was about to make the return journey that same evening.

The vote of thanks was accorded with hearty applause.

Mr. Swan Watson, in reply, said that if he could do anything for the Association he was always glad to do it, though he often felt that the long distance which separated him from London made him of necessity an indifferent president.

The Council meeting then concluded, after a session of 3¾ hours.

Glasgow and West of Scotland Society of Professional Photographers.—A very successful smoking concert was held in the Lansdowne Restaurant on Wednesday, November 23. The president occupied the chair, and there was an attendance of between 40 and 50 members and friends present. An excellent programme was submitted, the talent of the artistes being of exceptional merit. During the evening the president, on behalf of the members, presented Mr. Romney, jun., the retiring secretary, with a wallet of notes, and, in a few remarks, expressed the Society's indebtedness to Mr. Romney for the conscientious and very efficient way he had carried out the duties of hon. secretary and treasurer. At the close of a very enjoyable evening, Mr. Fairbairn, after thanking the chairman for presiding, proposed a vote of thanks to the artistes for their services, and the meeting concluded with the singing of Auld Lang Syne.

Commercial & Legal Intelligence.

Legal Notices.—A second and final dividend of 2s. in the £ has been made in the case of Charles Walter Bendel, fine art dealer, 34, Darlington Street, Wolverhampton. The dividend is obtainable at the Official Receiver's Office, 30, Lichfield Street, Wolverhampton.

Ilford, Limited.—The net profit of Ilford, Limited, for the year ended October 31 was £41,552, and £10,929 was brought forward, making £52,481 for appropriation. The directors have transferred £4,000 to reserve fund, and written £6,000 off goodwill; and a dividend of 8 per cent. is recommended on the ordinary shares for the year, leaving £6,281 to be carried forward.

Aldershot Photographer's Affairs.—At the offices of the Official Receiver, Russell Square, W.C., on Wednesday last, the first meeting of creditors was held of Frederick George Hookway Gould, of 19, Station Road, Aldershot, photographer, against whom a receiving order was made on November 10, 1921, on the debtor's own petition. The statement of affairs showed liabilities expected to rank for dividend amounting to £482 7s. 1d., and the assets were all absorbed by preferential claims. The causes of failure, as stated by debtor, were lack of custom caused by the absence of troops, thereby reducing turnover by more than 50 per cent., and moneys unaccounted for (£55) by two employees. The Official Receiver's observations on the case were to the effect that the debtor, in 1906, commenced business without capital as a photographer, at 19, Station Road, Aldershot. Since the troops left Aldershot in 1918 his business has declined, and in March, 1921, his creditors began to press him for payment, and that five creditors for £157 issued legal processes against him. On October 6, 1921, he held a meeting of his creditors, and offered to pay £30 down and £5 per month until 20s. in the £ had been paid, but his principal creditor refused to agree, and the offer was not proceeded with. The unsecured indebtedness includes £75 to the debtor's wife for money lent in 1912, £110 to his daughter for money lent in 1918-1920, and £295 7s. 1d. to trade creditors. The estate was left in the hands of the Official Receiver.

News and Notes.

THE "QUEST" PHOTOGRAPHER.—We understand that Mr. Jack Ross, the cinematographer, was chosen for the Shackleton Expedition to take the place of Mr. J. C. Bee Mason, who had to return owing to ill-health. Mr. Ross, who sailed last week, is a South African.

FACES FROM A "NEW ANGLE."—A writer in one of last Sunday's papers states that some of the portraits made by Sir William Orpen can be described as "living portraits," and that he owes his success as a portraitist to his characteristic habit of looking at familiar faces from a new angle.

POULTRY PHOTOGRAPHS.—Messrs. Meatmaco, proprietors of a food for poultry and other live stock, are offering cash prizes to the value of £100 for the eight best photographs of birds fed with Meatmaco. Particulars and entry form of the competition may be obtained on application to the firm at Eves Place, Borough High Street, London, S.E.1.

THE CLUB PHOTOGRAPHER, in its issue of December, presents contributions by members of the Plymouth Photographic Society—on flashlight, night, aerial and Press photography. Among the general contributions are notes on Bromoil transfer by James Rowatt, and on soft-focus lenses by Henry M. Holland. Our energetic contemporary is published at 9, Eberle Street, Liverpool, price 3d. monthly.

PHOTO-MICROGRAPHY OF PAINTS.—In the current issue (November, 1921) of the "Journal of the Franklin Institute" is a detailed contribution by Henry Green, of the Research Laboratory of the New Jersey Zinc Company, describing the means adopted for determining the size of the particles in paints and in rubber pigments by a photo-micrographic method. On other pages of the same issue the technics of electric welding are profusely illustrated by photo-micrographs. As we have occasionally pointed out, a thorough acquaintance with practical photo-micrography is one of the qualifications of a works photographer which is rapidly becoming of greater importance. Nowadays it is almost always observable that a piece of industrial research, carried out for the purpose of improving a manufacturing process, depends largely upon the services of the photo-micrographer

FOREIGN PHOTOGRAPHIC LENSES.

To the Editors.

Gentlemen,—We have read Mr. Browning's letter in your issue of November 18. As we represent the firm of Goerz in Great Britain we hope you will give us the opportunity of adding one or two points which, perhaps inadvertently, were omitted by Mr Browning, and the absence of which might lead to wrong conclusions.

We think that it is possible to construe the letter so as to give the impression that the Goerz lens mentioned was a pre-war article, purchased comparatively recently from Goerz's agency. This is not the case, as the number referred to, viz., 118,054, was manufactured some time between June, 1901, and April, 1904. This fact can easily be verified because information in our possession shows that the 100,000th Goerz lens was made in March, 1901, and all series III Goerz lenses made after April, 1904, were engraved with the word "Dagor," and bore higher factory numbers. In these circumstances it would seem that the lens in question is over seventeen years old, and that many things may have happened to it since then to upset its corrections and performance, and that it is being compared with lenses which have been manufactured within the last two years. It is not usual, when making comparisons, to choose one instrument, which presumably has been subject to many years wear and tear, and the others almost new from the makers

We do not impugn in the slightest degree the accuracy of the N.P.L. certificate, but we do think it is a wise policy to be fair, even to one's bitterest enemy, and that material facts should be disclosed. We venture to suggest that had the lens been tested when new the result would have been entirely satisfactory.

We might further mention that in the past not one, but many dozens of Goerz lenses have passed the National Physical Laboratory tests perfectly satisfactorily, and that we have before us, at the moment of writing, one such certificate which is at least equal to the other two mentioned by your correspondent.

We say this without in any way reflecting upon the other lenses mentioned, which are known to be quite good.—Yours faithfully,

For PEELING & VAN NECK, LTD.,
R. E. Peeling, Director.

4 to 6, Holborn Circus, London, E.C.1.
November 22.

To the Editors.

Gentlemen,—Having read with interest Mr. K. C. Browning's letter, "Foreign Photographic Lenses," in your issue of the 18th, and the letter in your issue of the 25th, above the nom de plume "Amateur," we take the liberty of encroaching on your valuable space to say that we, as among the largest manufacturers of photographic and cinematographic lenses in this country, have consistently advertised for years past that we are prepared to forward any Dallmeyer lens on seven days' free trial in order that prospective customers may make a comparative test, or if desired, forward to an authority, such as the National Physical Laboratory, for test and full report. We have no record of any photographic or cinematographic lens being so forwarded and rejected.

We recently at the request of the Secretary of the Royal Geographical Society despatched certain photographic lenses of the anastigmat and telephoto types to the National Physical Laboratory for comparative tests against other makes of lenses (country of origin unknown to ourselves). All lenses were passed, and were duly purchased and used by the Mount Everest Expedition of the Royal Geographical Society in conjunction with the Alpine Club.

With regard to the suggestions that all lenses over a certain value should be sent as a matter of course to the National Physical Laboratory, while we recommended the above course in a competitive test of such importance, we find that in general customers are satisfied with our workshop tests, and we hesitate to add the cost of a National test except where specially desired.

The case cited by "Amateur" does not refer to a lens of our manufacture.—Yours faithfully,

J. H. DALLMEYER, LTD.

Carlton House, 11b, Regent Street, S.W.1.
November 26.

A CONTRAST RATING FOR BROMIDE PAPERS.

To the Editors.

Gentlemen,—I have read the letters of Messrs. Hall and Taylor in your issue last week very carefully and I have failed to find any data which will enable them to establish their claim, namely, that the publication by the manufacturer of the exposure range or scale of the printing paper, under the title of contrast rating or degree of vigour, will place in the hands of the photographer information which will be a safe guide to the character of the finished print. They have asserted that the publication of this one item will indicate to the photographer not only what the "contrast" of the print will be, but that it will enable him to repeat that contrast upon another paper similarly rated. I tried to point out in my letter in your issue of November 18 that the exposure range of a paper was but one item among many which collectively determine the character of the finished print, and that we should require to be furnished by the paper manufacturer with several other measurements in order to be sure of obtaining successive batches of paper possessing similar printing properties. Having given reasons based upon the experimental evidence known to me, my opinion must necessarily remain unaltered in the absence of equally cogent reasons to the contrary. The statements in my previous letter admit of "practical" verification. It is a simple fact that *two printing papers of equal exposure range can yield two totally different prints from the same negative.*

The complexities of tone reproduction and the several measurable factors in any one printing paper which by their combined action determine the tones produced have received the attention of research workers to a considerable extent during the last few years. The

following references will be helpful to those who wish to become familiar with the subject :—

November 26.

To the Editors.

Gentlemen,—Having occasion to investigate the speed of bromide papers, tests of a number of different brands of paper were made by means of a Warnerke sensitometer.

Much to my surprise I found that the printing range of bromide papers did not necessarily bear any relationship to the speed of the papers. For example, a rapid paper requiring an exposure of one unit to produce the darkest black might show a printing range of fourteen blocks of the sensitometer, while another paper requiring an exposure of seven units would show a printing range of sixteen blocks.

This is quite contrary to the experience of those writers with whose works I am familiar, and seems to me to deserve investigation. I have made printing range plus speed tests of about twelve different makes of paper, and find that Wellington Cream Crayon, while by no means a fast paper, has the longest printing range.

Would it not be possible to persuade makers of bromide papers to stamp each brand of paper with a number showing the printing range obtained by means of a recognised standard step sensitometer?—Yours faithfully,

A. KNAPP.

October 26.

THE PAGET PROCESS OF COLOUR PHOTOGRAPHY.

To the Editors.

Gentlemen,—We have read in your issue of November 25 the report of the meeting of the Croydon Camera Club, at which Mr. Newens gave a lecture entitled "Rambles with the Paget Colour Plate." In this report it was argued that because Messrs. Ilford and Wratten both issued with their panchromatic plates a card showing the ratio of sensitiveness of the plates to each primary colour, the Paget Company should issue a series of filters suitable for their colour process, and should state with each batch of negative plates which of these filters should be used for the particular batch of plates. The reason this is totally unnecessary with the Paget colour negative plate is because the ratio of sensitiveness to the three primaries is absolutely constant in every batch of these plates issued.

Furthermore, the Paget colour negative plate is manufactured solely for use with the Paget colour process, and is as much an essential as the taking screen itself. The plate is not intended for the same uses for which other brands of panchromatic plates are made. If this ratio were not constant, the Paget colour process would either be most unsatisfactory, or else some suggestion, such as made above, would have to be adopted. Even so, it would be extremely unlikely that a sufficient number of filters could be issued which would adequately meet all variations of sensitiveness in the negative plate.

We consider also that if there was the necessity for such a large range of filters, the impracticability of selection would be so great as to render the process impossible. The fact that the ratio of sensitiveness of Messrs. Ilford's or Wratten's plates is not constant, thereby entailing the issue of a ratio card, proves that these plates are not suitable for the Paget colour process, and we feel sure that both Messrs. Ilford and Wratten would be the first to endorse this statement. We hope that this will show that no panchromatic plate, however good it may be for the correct reproduction of colour in monochrome or three-colour half-tone work, suitable for use with the Paget colour process, except that which is made especially for the process by the Paget Company.—Yours faithfully, PAGET PRIZE PLATE CO.

Watford, Herts,
November 28.

To the Editors.

Gentlemen,—With reference to the notice you so kindly gave of my talk on the Paget colour process at the Croydon Camera Club in last week's "B.J.," may I correct one or two slight but rather important errors therein?

1. The Sanger Shepherd graduated filter was used *in addition to*, and not "instead of" the orthodox Paget filter;

2. The roughened edges of the negative emulsion is removed with a sharp knife before the transparency is made from it, and not before placing it with the taking screen in the dark slide though I might have amplified this point and suggested doing likewise to the lantern slide before registration with viewing screen; and

3. The suggested filters to be available for serious workers should be for "any particular *batch*," not "box" of plates.

I do not suggest that the "B.J." report was inaccurate, the slip may well have been mine, for, as you were good enough to point out, the failure of the electric light rather threw me upon my own resources, and I was obliged to "carry on" without previous preparation or notes of any kind.—Yours truly,

FRANK R. NEWENS.

50, Elmwood Road, Chiswick, W.

Answers to Correspondents.

Queries to be answered in the Friday's "Journal" must reach us not later than Tuesday (posted Monday), and should be addressed to the Editors.

C J. RUSSELL.—The sitter is entirely within his rights in objecting to the display of the portrait in the window. As owner of the copyright no one else but him has the right to print from the negative, or exhibit such prints without his permission.

A. E. T.—Although the D.50 solution contains free sulphurous acid, this latter is neutralised when the stock solution is compounded with the soda carbonate of the formula, and, therefore, it is just as correct as with any other developer to use an acid fixing bath for arresting development.

F. W.—Several roll films may be developed at one time in a vertical tank of depth a little greater than the full length of the films which are held in the developer by clips attached to rods laid across the top of the tank, and are kept free from one another by being weighted at the bottom end. Films are commonly developed in this manner by those undertaking the development and printing of amateurs' film negatives.

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 3214. Vol. LXVIII. FRIDAY, DECEMBER 9, 1921. Price Fourpence.

Contents.

SUMMARY.

The 1922 "B.J Almanac" will be published throughout the United Kingdom on Monday next, December 12.

At a recent meeting of the South Suburban Photographic Society, the president, Mr. P. R. Salmon, delivered an address on the modern history and manipulation of self-toning papers. He traced the introduction of self-toning papers in this country, and presented, in a compact form, a large amount of practical experience in the use of the many makes of self-toning paper at present on the market. (P. 730.)

In a contributed article Thermit gives working instructions in the making of warm-tone prints by direct development with pyro soda. The developer recommended has a further usefulness for the production of a P.O.P. tone when used as a re-developer of bleached bromide or gaslight prints. (P. 727.)

In a recent paper before the Royal Photographic Society, Mr. Olaf Bloch showed the advantage, as regards evenness of development, of applying the developer by a velvet-covered roller. (P. 729.)

Dr. S. E. Sheppard, in a further paper, which deals with the effect of iron impurities on the action of the persulphate reducer, finds that the acidity of the reducer greatly affects the influence of minute traces of iron. It would seem that if the reducer is acidified, as directed by MM. Lumière and Seyewetz, the irregularity which may be caused by impurities in commercial persulphates is counterbalanced. (P. 726.)

Mr. Lang Sims, secretary of the Professional Photographers' Association, announces that the 1922 Congress will be held in Princes Gallery, Piccadilly, London, W., in September next. (P. 739.)

Mr. Ernest A. Dench describes a number of schemes of window dressing employed by portrait photographers in the United States and Canada. (P. 728.)

In a leading article we draw attention to the almost hopeless state of confusion which prevails as regards copyright in China, particularly as regards infringement by nationals of various countries. (P. 726.)

In reference to the use of Transferotype paper for negative making, Messrs. Pictorial Machinery, Ltd., inform us that they supply an extra contrasty Transferotype paper specially made for them by the Kodak Company, and yielding, when developed, etc., as they direct, negatives of wet-plate character. (P. 738.)

M. Jules Carpentier, whose death has recently taken place, was a pioneer in France of the ultra-small camera and the designer of a number of refined models and of accessory apparatus. (P. 726.)

Particulars are given in a patent specification of a hand-camera folding to extreme slimness. (P. 734.)

Movement of the solution, whilst plates are being developed in a tank, is one of the chief preventives of markings. (P. 726.)

Dr. Traube has patented further improvements in his dye-toning process, providing great transparency of the dye-toned images. (P. 734.)

EX CATHEDRA.

The 1922 Almanac.

The 1922 volume of the "British Journal Photographic Almanac" will be published on Monday next, December 12. As in previous years, our publisher's arrangements have been carried out so that the book shall be on sale simultaneously throughout the United Kingdom on that day. Dispatches to the Provinces are, of course, made in advance on the strict understanding that the book is not offered for sale until the appointed day of publication. Dealers are requested particularly to observe this condition of supply. Within the London area distribution takes place, in some cases, on the day of publication, and, while our publishers endeavour to secure rapid delivery on that day, it is obviously impossible for deliveries to be simultaneous; but dealers are informed that supplies leave the headquarters of our binders at 8 a.m., and are circulated with all possible expedition. As in the case of the last two years, the price of the Almanac in paper binding is 2s., in cloth binding 3s. If supplied by post these prices are respectively 2s. 9d. and 3s. 9d.

* * *

The Photographic Journal.

A word may be said by way of drawing the attention of readers who are not members of the Royal Photographic Society to the Society's "Journal," which has just completed its first annual volume subsequent to the appointment of the new secretary, Mr. H. H. Blacklock, in January last. During this period the "Journal," which previously had appeared at somewhat irregular intervals, has been published with clockwork regularity on the first of each month, with the exception of October, when its place is taken by the catalogue of the Exhibition. Commendable discretion has been exercised in curtailing those parts of its contents which are of more ephemeral interest, such as the reports of lectures on travel and similar subjects. While these discourses are of interest when heard to the accompaniment of their lantern illustrations, they lose much of their value in print, and the Society has been wise in allocating a smaller proportion of its space to reports of them. This policy has rendered possible a correspondingly greater assignment of space to the technical and scientific papers and communications which the Society has received during the year, largely through the medium of its Scientific and Technical Group. Thus at the end of the year we find the pages of the "Photographic Journal" to contain communications relating to scientific and technical advances in photography, many of which are not to be found elsewhere, and where also the reader is able to study the discussions which have followed them. The "Journal" is supplied to non-members of the Society at the price of 35s., but, as the annual subscription is only two guineas, most people will take the course of obtaining it as members of the Society.

Developing Tanks. Tank development seems to be gaining steadily in favour among all classes of photographers, who are doubtless becoming more fully alive to the advantages of this system, and failures, in the form of streaks, uneven action of the developer, stains, etc., seem to be far less common than formerly. One point, however, may be noted in this connection, since it is one which often is not realised until the worker is forcibly reminded of its necessity by a batch of unevenly developed negatives. We refer to the necessity of agitating the developer in some way several times during the period of development. In the case of the smaller tanks the best way is to take them up bodily and rock them backwards and forwards several times. Larger or heavier tanks may have the plate racks lifted up and down several times, this movement serving the same purpose. Some tanks upon the market are fitted with a means of keeping the solution agitated, though there seems room for improvement in this direction. One photographer that we know has a rubber bulb fitted to the top of a brass tube which runs down and enters the tank at the bottom, with the result that gentle pressure of the bulb causes air to enter the tank at the bottom and agitates the developer very effectively. This is the plan adopted by one of the best-known makers of amateurs' film tanks upon the market, and the principle might be more widely employed.

* * *

A Pioneer of the Small Camera. By the death of M. Jules Carpentier there passes away an eminent French mechanician to whom must be ascribed the development on the manufacturing side of the ultra-portable cameras of the present day. M. Carpentier was an engineer by training and profession, who afterwards took up the manufacture of electrical instruments of precision. Following an old interest in photography—he was a collaborator with Cros in three-colour work—the year 1890 witnessed his design of a camera of about the present vest-pocket size, taking twelve plates in an ingenious changing box, and providing for the focussing of objects up to within seven yards. Subsequently, M. Carpentier extended the number of models and applied the same fine mechanical workmanship, which characterised the cameras, to the making of a fixed-focus enlarger by which the production of large prints was rendered as easy as contact printing. He extended this idea into an enlarger of variable extension for different degrees of enlargement, and later into one in which the convergence of lines, due to tilting of the camera, were automatically corrected in making the enlargement. He was also a designer of instruments for setting the lens in the most accurate position of focus on hand-cameras, and also for measuring the speed of shutters. Apparently, the peculiar square pyramidical form of camera, which has remained popular in France as the "jumelle," was his original design. Many other scientific instruments for photography were made by him, among them the cinematograph apparatus designed by M. Louis Lumière in the year 1895, which was the first efficient equipment for the making and taking of animated photographs.

* * *

The Persulphate Reducer. Dr. S. E. Sheppard communicates from the Eastman Research Laboratory to the December issue of the "Photographic Journal" a lengthy paper on the inexhaustible subject of the theory of the persulphate reducer. No useful practical purpose would be served in endeavouring to present an abstract of the whole communication, but reference may be briefly made to that part of it which relates to the effect of small quantities of iron salts, such as may occur as impurities in commercial samples of persulphate, upon the action of the reducer. A year or two ago ("B.J.," July 12, 1918, pp. 314-315) Dr. Sheppard, in a short paper, ascribed the activity of the persulphate reducer to the presence of minute traces of iron salts. This view was actively contested by MM. Lumière and Seyewetz in a paper which we published in our issue of March 4, 1921, pp. 124-125, where it was stated, as the result of further experiment, that iron salts were without effect, provided that the persulphate solution was of the required degree of acidity. MM. Lumière and Seyewetz prescribed that the reducing solution should contain from 0.25 to 0.50 per cent. of sulphuric acid. Dr. Sheppard, in his last paper, now shows that the accelerating effect of iron salts on the persulphate reducer varies very greatly with the acidity of the solution. He states that their action is definite when quantitatively measured in a solution containing 0.25 per cent. of sulphuric acid, but imperceptible in one containing 0.50 per cent. of sulphuric acid. So on this point we appear to have reached substantial agreement between him and MM. Lumière and Seyewetz. Other factors appear to be concerned—Dr. Sheppard discusses them freely—but the practical conclusion seems to be that if you add to the working persulphate solution a proportion of sulphuric acid, which may be as much as ½ per cent.—that is to say, about one or two drops of the strong acid per oz.—the varying effects of impurities are counterbalanced—at any rate, sufficiently for ordinary purposes.

COPYRIGHT LAW IN CHINA.

The law of copyright, as our readers know, has its obscurities in this country, but its state here, or even throughout Europe, is of crystal clearness compared with that which prevails at the present time in China. The importance of copyright law in China may appear somewhat remote at a first glance; that is to say, until it is realised what enormous markets await commercial development in that country. The Chinese Ambassador in London, Dr. Wellington Koo, in a recent address to Chinese students, quoted figures showing the tenfold and hundredfold increase of American trade in China, chiefly in metals and engineering goods. In any trade, in countries where there is competition by Oriental merchants, facilities for the adequate protection of copyright in designs, trade literature, and other pictorial accessories to the sale of goods, play a by no means unimportant part in the way of restricting the passing off of inferior articles as those of manufactures of repute. It is therefore of interest to obtain some insight into the present state of copyright law in China, and so we take the opportunity of putting into an abridged form an analysis of the question which has been prepared by the Associated Chambers of Commerce in Shanghai and Hongkong.* The question is of extraordinary complexity, since it involves not merely legislation as regards copyright, but also the judicial powers exercised within Chinese territory by the authorities of the various countries having a finger in the pie of Chinese government. Thus, the conditions vary according, as, for example, the infringer of a copyright may be of Chinese, Japanese, American or British nationality.

It appears that China has some kind of copyright law, promulgated in 1910, renewed in 1915, and supplemented in 1916. But this law does not give protection to British

* British Chamber of Commerce Journal (Shanghai), New Series, No. 30, October, 1921, pp. 330-333.

subjects, or to any other foreigners, except in so far as the countries to which they belong have made reciprocal arrangements with China. America has entered into such arrangement to a limited extent, but Great Britain has not done so, and therefore at the present time a British subject in China is without the power to prosecute a Chinese subject for infringement of copyright. Apparently, a remedy for this state of things is a very complicated business, involving considerations of international law and treaties. A reciprocal arrangement, together with improvement of the Chinese copyright law, would improve matters so far as infringement by Chinese subjects is concerned. But that would be only a very partial remedy, because it would provide no means of taking action against Japanese infringers, for the reason that China has no jurisdiction over Japanese subjects in the country, actions against whom are heard in Japanese courts. By a reciprocal arrangement between England and Japan, infringements taking place in Japan can obtain a remedy, but under the terms of the Anglo-Japanese commercial treaty that remedy does not apply to Japanese subjects in China. The conclusion from this is that for adequate protection of British copyrights in China it is first of all necessary to obtain an Anglo-Chinese treaty on the subject (which would provide protection against infringements by Chinese) and also to obtain agreement of all the Powers having treaties with China to China's copyright law. But even the latter arrangement, if it could be successfully carried out, would still leave vital judicial difficulties unsolved.

The question is further complicated by the uncertainties which prevail in regard to the question whether British subjects have a legal remedy, under the 1911 Copyright Act, in respect to infringement in China by other British subjects. The provisions of the 1911 Act itself offer a copious field of argument for international lawyers. Although in some respects the Crown has the same jurisdiction in China as it would have in conquered or ceded territory, yet it is not possible to say that the rights conferred in this country upon a British subject under the 1911 Copyright Act are conferred upon British subjects in China, and it therefore follows that the reproduction in China of a British copyright work by some other British national is not an infringement of any right. Moreover, such Orders in Council which have been applied to Chinese territory apparently do not provide for the application of the whole of the Copyright Act, but only of the penal provisions. Cases have been heard in the British Courts of China which have been decided in accordance with this view. The general conclusion which is reached by the Associated Chambers of Commerce, as regards this branch of the subject, is that it cannot be definitely maintained that the Copyright Act applies between British subjects in China. It will thus be seen that firms having a present or future interest in the Chinese market will be well advised to link themselves with the larger commercial organisations whose business it is to watch developments in these directions and to use their influence for obtaining even some partial improvement on the confusion which exists at the present time.

WARM-TONE PRINTS DIRECT.

When one considers the undoubted popularity of warm black prints on development papers, it seems strange that the principle which is exploited to produce this class of print has never been commonly extended.

The papers used by professionals for this work are almost exclusively of the kind known as "slow development." Not a very good name, considering that ordinary bromide paper under normal conditions usually takes longer to develop. I have heard these papers also called "chloro-bromo," but would not like to say that the term was appropriate to all such papers. For the present purpose I will keep to "slow development."

But slow-development emulsions are not the only ones capable of giving colours direct. Warm blacks, sepias, and even reds can be obtained in the same way from many grades and kinds of developing papers. The use of bromides and gaslights for this work, and the extension of the process to the production of vandyke brown and red chalk, have been restricted to amateurs and experimenters up to now. The process is simple enough though, and the results obtainable can be all that the most fastidious would wish for.

The principle of the method I am going to describe depends on vigour, the vigour of the negative and the vigour of the paper. The developer is a pyro formula specially designed for the process, viz:—

Soda sulphite (cryst.)	.....	1 oz.
Potass. metabisulphite	.....	20 grs.
Pyro.	.....	60 grs.
Potass. brom.	.....	60 grs.
Soda carbonate (cryst.)	.....	1 oz.
Water	.....	20 ozs.

Made in one solution, this developer must be used soon after making up; for keeping purposes, it is necessary to divide the water and dissolve the carbonate separately. An elaboration which is useful when first trying the process is to dissolve the bromide separately also in about ½ oz. of the water and to add it tentatively to the rest while making trial prints, as some combinations of negative and paper may not require the full amount.

The grade of paper, whether it be bromide, gaslight or slow development, must be selected in respect to two considerations. These are, the contrast of the negative and the final colour of the print. Vigorous papers are best for general use, but the more contrasty the negative is, the less is the essential vigour of the paper, while the warmer or redder the desired tone is, the greater the necessity for vigour in the paper, the ideal combination for a red chalk being a hold negative and a vigorous gaslight paper.

Given our negatives and papers, and having made up a quantity of developer, we proceed in this fashion. Should a negative be weak, whatever the colour desired, we take our most contrasty grade of paper; but if the negative is hard, and the desired tone not very far removed from black, a soft or normal grade of paper will be better. Exposure must be great. There is no case of "development to finality," nor, without experiment and calculation, can a system of time or factorial development be used. As I have been content up to now with inspection, I cannot give any figures for the more systematic methods. It can be taken for granted, however, that in every case exposure must be what would in any other process be excessive. For tones of a warm black or dark brown nature slight over-exposure may be sufficient. For warm browns and reds much greater exposure is required, quite a range of colours being possible with the same combination of negative, paper and developer, merely by altering the exposure. There is a limit, however, and should the four factors not agree, disagreeable tones will result. These bad tones usually point to want of vigour somewhere, and can be obviated by using a more vigorous paper. When conditions

are ideal a print will reach its correct depth and correct colour simultaneously, when it must be snatched out of the solution and plunged into an acid fixing bath. Under-exposed (for this particular purpose) prints will not reach anything like a warm tone, though they can be developed to a good black, as a rule. Over-exposed prints are apt to be muddy and of a nondescript colour at the best. Between the two there is a much longer range than exists with any orthodox system of print making.

The appearance of prints made in this way has a different significance to that of those made in any other development process. Good prints look just right when they are lifted out of the developer for removal to the fixing bath, though some allowance has to be made for the yellow illumination which falsifies colours seen by it. As very strong yellow light is safe with most papers under the peculiar conditions, this falsification can be balanced somewhat by using increased illumination to inspect by. On immersion in the fixing bath a change takes place in the strength and colour of the print, the change being slight with warm black prints and marked in the case of red or brown prints. So great is the change with brick-red tones that a printer might be excused for scrapping the prints and the process forthwith, but it is only necessary for the prints to wash and dry to regain their full strength and colour.

The pyro formula given above has a further use. As a re-developer for bleached bromide or gaslight prints it yields a tone that cannot be very well got in any other way on these papers. It is the colour known to expert printers of P.O.P. and called by the public—we are told—"the real photo colour." Bleaching can be done the same way as for sulphide toning, and any recognised bleaching formula used.

The permanence of prints which have been developed or re-developed to brown or red has been questioned. As the image consists of nothing but pure silver, there is no reason to suppose it to be impermanent. The only difference between the coloured image and a black and white one is that it is deposited in a different way, and consists of finer particles. The stability of the two deposits can be practically tested by taking a forced black and white print, and a brown or red one made in the above manner, and treating them with a reducer or bleacher. It will be seen that the deeper lying black deposit resists action better and longer, which leads to the supposition that the coloured images are the more delicate. Therefore care must be taken not to leave hypo or alum in the gelatine of the prints when putting to dry, or they will "fade" more rapidly than black and whites would. In other respects the coloured deposits are practically as permanent as other silver images, and it would be straining at a gnat to neglect the process on grounds of possible instability.

The coloured image has a physical, or perhaps colloidal, peculiarity, however, being subject to change under the influence of great heat. Care has to be taken therefore if dry-mounting these prints.

THERMIT.

THE STUDIO PHOTOGRAPHER'S RESTRICTED DISPLAY FACILITIES.

THE studio photographer's window display facilities are generally restricted in scope. If he maintains an upstairs establishment his display consists of a window case in the doorway.

It is with these restricted display facilities in mind that the following notes on unusual displays have been compiled:—

L. H. Merry, Hollis, Me., devoted a display to children's pictures. The principal object of attraction was the wax figure of a baby, who sat on a fur rug while playing with her dolls and other playthings. At the opposite side was a tripod camera, focussed in the direction of the child. The central window location contained two cabinet photographs. The first picture showed the child, as in the setting described, playing with her toys, while the contrasting picture revealed the youngster in a straight and stiff-like pose. Backing up the exhibit was the following card:—

"You want your kiddies to look happy. Bring them in and we'll make them happy."

Flagg and Plummer, Lewiston, Me., also appealed to grown-ups via the juvenile route. Charming photographs of adorable looking children were grouped on the floor over billows of pink satin. A card announced that:—

"Your children are just as cute as these. Give us an opportunity to prove it."

Longs, Photographic Studio, Seattle, Wash., displayed a row of baby pictures. There were seven such photographs in all and in graduating sizes. The unique feature was that the seven pictures were all of the same baby. The miniatures and enlargements were flanked in the middle by the original picture. A sign inquired:—

"What do you think of our baby show?"

Kosch, White Plains, N.Y., laid a number of unframed photographs at regular distances apart on the green crepe paper-covered window floor. Each picture was covered over with a small sheet of glass of the same size as the photograph. This served to attract attention to the photographs.

The Scottish Studio, Montreal, Canada, stimulated business by an offer which was given publicity on a sign outside their second-storey window. The sign read:—

"Children between 1 and 5 photographed free by appointment."

The idea, of course, was that doting parents would not be satisfied with one free photograph, but would require probably several dozen copies in order to satisfy the demands of relatives and friends.

Steele, Saskatoon, Sask., Canada, inserted a convincingly-worded framed showcard in his outside window case. The announcement ran:—

"The children won't stay little long. Have them photographed at Steele's Studio."

The photographs exhibited in the window case consisted of two photographs of the same child at different times. There were several such examples, captioned like this:—

"Age 17 months—age 3 years. Barbara Haining."

McDermid, Edmonton, Alta., Canada, devoted the space in his window case to pictures of juvenile birthday parties. On a card appeared the invitation as below:—

"Bring your children for birthday pictures."

Mrs. Mason, Moose Jaw, Sask., Canada, closes her studio during the dull summer months while she takes a well-earned vacation. She gets her patrons in the habit of deferring their sitting by the following appeal:—

"NOTICE.—This studio will be closed until the first week in October.

"WAIT.—We will be back with new ideas and renewed energy."

The Harper Studio, Medicine Hat, Alta., Canada, is a liberal user of newspaper advertising, an effective example of which is given below:—

"The making of high class portraits is not a mere chance
Nor can the art be learned in a few years.

Anyone with a little practice can make photographs of a kind, but to make portraits that give you the true rendering of flesh tones and character takes a lifetime of continual study."

Miss Tawdry, Calgary, Alta., Canada, imparted local interest to her window case by exhibiting the photograph of the first prize winner in the local kitten show. "How adorable," "Isn't he cute," were some of the comments from passers-by.

Stocks, Penticton, B.C., Canada, took advantage of a local autumn exhibition by offering to take a free picture of every baby entered in the baby clinic at the Penticton Exhibition.

The Regal Art Photo Studio, Vancouver, B.C. inaugurated a title contest, in connection with which prizes of free sittings were offered. All the contestant had to do was to apply an appropriate title for a large picture exhibited in the window case. The subject was that of two dogs with an air of expectancy on their faces.

F. L. Hackney, Vancouver, imparted an autumnal touch to his window case by placing therein a bronze vase filled with yellow chrysanthemums. Portraits lined the walls, with the following card at the centre:—

"You are now educated to the high standard of a Hackney portrait. But do you realise how reasonable the price may be?"

ERNEST A. DENCH.

THE UNIFORM DEVELOPMENT OF DRY PLATES.

(A Paper read before the Royal Photographic Society.)

It is well known that development is essentially a diffusion phenomenon, and that in consequence it is not easy to secure a uniform density over even a small area since development is most efficient at the edges of the plates as the amount of reaction product of development tends to accumulate towards the centre of the dish. Unless the plate is both

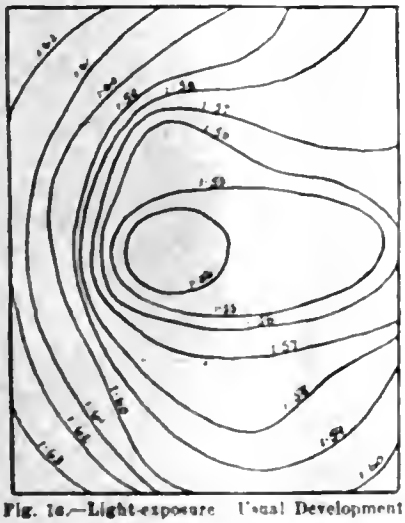

Fig. 1a.—Light-exposure: Usual Development

evenly coated and evenly dried, these defects also give rise to irregularities in the developed density. Cailler[1] has given some data which show how serious are the departures from uniformity. Various methods have been devised to overcome this trouble,[2] and some which have yielded good results in their originator's hands have not been so successful in the hands of others. With light-exposures very slow rocking of the plate successively in four directions at right angles to each other, uncovering half the plate at each rocking, gives fairly good results.[3] With X-ray exposures the latent image does not lie principally near the surface, but is distributed through the depth of the emulsion, and irregular rocking has been recommended.[4] In carrying out some work on the behaviour of plates to X-rays[5] it was found that the variable results obtained were due to irregularity of development, and experiments led to the adoption of a method of rolling development which enabled consistent results to be obtained.

In order to illustrate the problem the following experiments have been made. Sheets of patent plate, 15 by 11¼ cm., were heavily coated with ordinary and X-ray emulsions, and, after setting on a level slab, dried in a special cupboard arranged to give the most even drying it was possible to obtain. Those coated with ordinary emulsion were light-fogged, using a small light-source at a distance of 250 cm., and those coated with X-ray emulsion fogged by X-rays, using a small stop and working 180 cm. from the tube. The plates were thoroughly soaked in water before development. In each case one plate was developed by the rocking method (irregular in the case of the X-ray plate) and one by the rolling method. The plates were ruled off into squares, the densities of each square carefully measured and the isopaques plotted out.

Fig. 1 shows the results in the case of the light-exposed plate. It will be seen that with the usual method of development a region of greater density prevails round the edges of the plate, falling away towards the centre, sometimes complicated by other irregularities. This is due to the greater concentration of soluble bromide, set free in development, in the central portion of the plate which the usual methods of development fail to remove with sufficient rapidity. The use

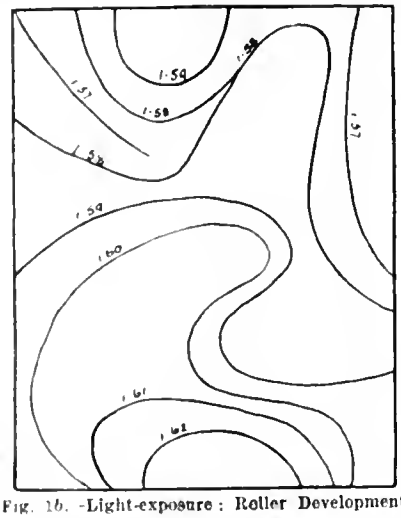

Fig. 1b.—Light-exposure: Roller Development.

of a developer containing large quantities of bromide overcomes this trouble, but such a developer is not at all suitable for most sensitometric work. The range of densities in the rocked plate is considerably larger than in the roller-developed plate, where it will be seen that the density distribution is of a far more satisfactory character.

Fig. 2 illustrates a similar pair of X-ray exposures. Here

1. Cailler, "Phot. Journal," *55*, p. 242.
2. Sheppard and Mees, "Investigations on the Theory of the Photographic Process," p. 34.
3. Renwick, "Phot. Journal," *52*, p. 254.
4. Wilsey, "Am. Journal of Roentgenology, 1921," *8*, p. 328.
5. Bloch and Renwick, "Trans. Faraday Society," *15*, Part 2, 1919.

the rocked plate exhibits the same characteristics as in the case of Fig. 1, whilst the roller-developed plate gives a more rational density distribution, the wedge-shaped gradient indicating lack of uniformity in the coating, the coating thickness rising across the plate diagonally.

The details of the method are as follows. The rubber cover-

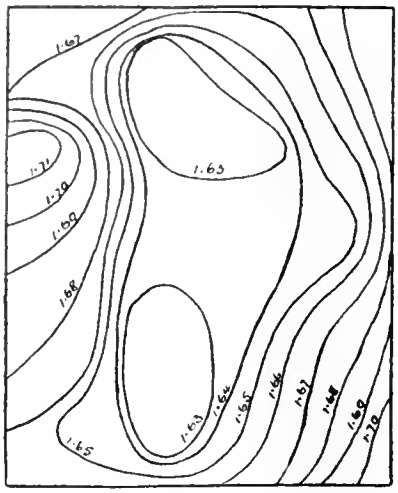

Fig. 2*a*.—X-ray Exposure: **Usual Development.**

ing of an ordinary roller squeegee (rather wider than the plate to be dealt with) is removed and the wooden cylindrical core covered with a strip of heavy pile velvet which is wound spirally around it. The velvet is secured by small brads, care being taken to see that the heads of these are quite at the bottom of the velvet. After the roller has been well soaked in some of the developer the rest is poured over the plate in the usual way, and slow and steady rolling over the surface of the plate commenced at once and continued until development is completed. No pressure must be used, and the roller should be alternately passed across the face of the plate in two directions at right angles to each other. The roller assists in the removal of exhausted developer from the upper surface of the plate and helps to apply fresh developer in its place, thus tending to equalise the concentration over the whole plate area.

The control of temperature is not so easy as with those methods of development which permit the use of a thermostat, and it will be found advisable to work at the temperature of the dark room. The work here described was conducted at 18.5 deg. C. In the case of emulsions, where the gelatine is at all soft, care must be taken that the developer is not warm enough to so soften the film that it becomes abraded by the rolling process.

In conclusion it may be said that the method affords an easy means of securing more uniform development than can be obtained by the ordinary methods in those cases when great accuracy is desirable. My best thanks are due to Messrs.

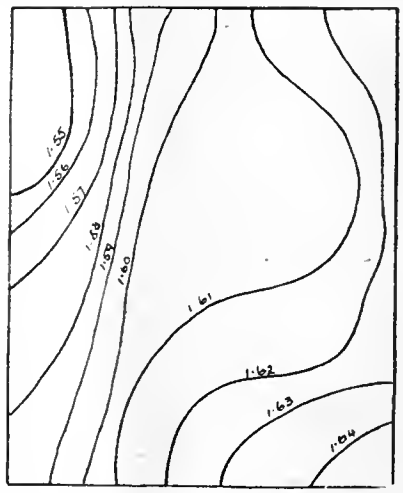

Fig. 2*b*.—X-ray Exposure: **Roller Development.**

Ilford, Ltd., in whose laboratories these experiments have been conducted, and to Mr. F. F. Renwick for his advice and interest in the work.

OLAF BLOCH, F.I.C.

THE MODERN HISTORY AND MANIPULATION OF SELF-TONING PAPERS.

[The following paper formed the presidential address delivered by Mr. P. R. Salmon recently before the South Suburban Photographic Society. It will be seen that after a brief sketch of the commercial origin of self-toning paper the communication brings together a great deal of practical information of the working of the many self-toning papers at present on the market and on their characteristic effects.—EDS., "B.J."]

WHEN I consented to prepare some notes on the history and working of self-toning papers I had little idea of the big task I had set myself. The number of different brands at present on the market—there are no fewer than fourteen now "going strong"—is greater than I thought, while the brief historical part took longer to compile than I bargained for.

I am not aware of the existence of any information on the modern history of self-toning papers, and I trust my efforts to prepare one may be some service. The paucity of references concerning the subject is, I think, mainly due to the rather scant notice taken of self-toning paper during the first few years of its existence, also to the "quietness" of its coming. It had not the "boosting" that some processes, notably Bromoil, enjoyed later on. Another point is that self-toning paper came with—or very shortly after—gaslight paper, and it was the latter that attracted the attention of photographers, self-toning paper at its coming being looked upon as being suitable only for amateur photographers, who twenty-two years ago were not so numerous as they are to-day.

What few references there are to self-toning paper in the literature of twenty years or so ago are hidden away in odd corners, or are too insignificant for indexing. One has therefore to rely largely upon one's memory, or wade through all the available journals, in order to supply all the links of the chain. Happily my memory is said to be good, and I distinctly remember the coming of the first self-toning papers of the collodion variety, but I must confess that during my searches in the journals I came across many items about self-toning papers and names of defunct brands that I had forgotten. It is therefore quite possible that I have missed some important facts; if I have, I have no doubt that someone will correct me.

Self-toning paper, however, did not originate in Germany, as the average photographer believes it to have done. Self-toning papers—of the modern variety at any rate—were "born" in America. I do not propose to discuss the much-debated question as to who was the real inventor of the paper. A Mr. D. Bachrach claims the honour (see "British Journal of Photography," April 20, 1906), but as Mr. E. J. Wall rightly pointed out ("B.J.," October 9, 1908, and April 8, 1921) there were others before him. The late Mr. John Spiller did something to bring about a self-toning paper.

In order to simplify matters, I do not propose to deal at any great length with the work of the early experimenters, or the many

varieties of sensitive paper that led to the making of collodion or gelatine self-toning papers of the perfect quality we have to-day. When mentioning early efforts I refer, of course, to plain salted and other papers—notably Ilford matt P.O.P. (1894) and Griffin's "Carbona" (1903), which gave excellent reddish brown tones when printed deep enough and afterwards fixed in plain hypo solution. This plan of finishing ordinary matt P.O.P. was at one time very popular, but one hears little of it to-day. Some studios made a specialty of such prints.

Mention may also be made of Rivet's self-toning paper, because it was, I believe, the first paper to be advertised as "self-toning"; it was an albumen paper, and quite different from the more modern self-toning papers. It was made at Willesden and appeared early in 1886, vanishing in 1900 when collodion self-toning paper was getting a footing in this country. Rivet's paper had to be very deeply printed; it was afterwards fixed in a plain hypo solution, washed, and then dried by placing between sheets of clean blotting paper and ironing with a hot flat iron until quite dry. The final tone was governed partly by the quality of the negative, and maybe a few other things, but most of all was it influenced by the amount of heat applied, a good "laundry-hot" iron giving the print a very pleasing purple tone, but sad to relate, the rich heat-given tone too often disappeared in a very short time. The paper, nevertheless, had many advocates, and was for a time a big success, an "improved" grade of it appearing in 1893. It was very popular among amateurs.

A remnant of this process of toning by heat remains to-day, for, as many no doubt know, the tone of prints on modern self-toning papers—particularly collodion—may often be enriched by placing the wet or dried print between sheets of clean blotting paper and ironing with a hot flat iron. This "dodge" is sometimes said to be a secret one and quite new, but it is in fact a very old one, known and practised in the early days of gelatine and collodion papers. Dr. R. A. Reiss, of Lausanne, investigated the question of the influence of temperature on tone very fully in 1900, and a summary of his experiments (which appeared originally in the "Photographische Chronik") may be found on page 963 of the "B.J. Almanac" for 1901. Self-toning papers are not mentioned in the experiments, only ordinary gelatine and collodion P.O.P., but the action of heat on self-toning papers may be said to be precisely the same.

To Mr. O. Sichel, of Bunhill Row, E.C., must be given the credit of first introducing a collodion self-toning paper of the modern type into this country. It came from America, and the first official or editorial notice of it appeared in the "B.J." dated November 4, 1898. This notice reads: "Some specimen prints on a new self-toning paper, which is being introduced by Messrs. Sichel and Co., have been submitted to us. The series of effects include glossy (resembling ordinary collodio chloride), sepia and platinum. The paper prints and tones simultaneously, and all the results are of excellent quality. A paper with such admirable characteristics should be widely welcomed." It will be noticed that the term "prints and tones simultaneously" was used, it being a common one at the time, as it was customary to combine printing and toning rather than toning and fixing. I have an idea, though I may be wrong, that this term was used by dealers because of the great outcry then prevailing against the use of the combined toning and fixing bath for ordinary P.O.P.

Messrs. Sichel's announcement of the paper was followed by one from Mr. Moult, who sold a "Kalos" self-toning (December, 1898), by Houghton's, who had an "Aura" brand (June, 1899), and also by Fallowfield. As instructions for the using of these papers were the same I think we may assume that Mr. Sichel was the distributor of the paper. This paper, as I have said, came from America, where it was manufactured, I am told, under a patent taken out by Schoenfelder and Kelly, of New York, and in our own Patent Office I have found three American specifications—two dated May 26, 1896, and one September 29, 1896—by the two workers named.

I do not propose to deal at any great length with the making of self-toning papers. Those photographers who are curious, and have a knowledge of chemistry, should refer to the "B.J. Almanac" for 1898, where on page 832 they will find one of Schoenfelder's patent specifications—the original formula, I believe.

A later specification (1903) is that of M. Bauer's, who was associated in some way with the first American self-toning paper (1896). The basis of the emulsion was fulminating gold, together with chloride and silver nitrate, citric acid, and glycerine dissolved in collodion. A report of the period (see "Photography," 1903, page 613) says of this patent: "A solution is made of 45 grs. silver nitrate, 45 minims of glycerine, in 150 minims of alcohol, which is added to 4 ozs. of collodion containing 3½ per cent. of soluble pyroxyline. To make the fulminating gold solution, take gold chloride 3 gr.; ammonia solution containing 26 per cent., 1 minim; lithium chloride or other soluble chloride, 3 grs.; to this is added a solution of citric acid 15 grs. in 1 drm. of alcohol, and then 15 minims of castor oil in 1 drm. of alcohol. Gelatine may be substituted for collodion, when, of course, water is the solvent instead of alcohol." Such is the emulsion for paper to be finished by means of salt and hypo solutions, or hypo alone. Similar formulæ appear to have been common at the time.

Self-toning paper, as we know, caught on, and Mr. Sichel's had a good run of several years. In course of time, however, the American manufacturers were unable to obtain raw materials for the making of the paper—owing, I am told, to the action of a rival firm—and rather than let a good thing die the patentees came over to this country, at the invitation of Mr. Sichel, for the purpose of arranging for the manufacture of the paper here. They were successful, for arrangements were made with the well-known Paget firm, of Watford, and on July 5, 1901, the "B.J." chronicled the advent of the "Paget" self-toning paper. The well-known house of Paget thus became the first British manufacturers of a "real" self-toning paper, a paper that has held its own and is still to be found in the front rank. Whether the original paper was made according to the American inventor's formulæ, or represented further improvements by the Paget firm, I do not know, but I imagine the latter.

Photographic experts then began to "sit up and take notice," and in the summary appearing in the "B.J. Almanac," 1902 (penned a few weeks after the introduction of the Paget paper) we get for the first time, I believe, an "Almanac" mention of self-toning paper and the progress it was making, and in the same volume (page 901) will be found a patent of "an improved self-acting toning paper" taken out (in 1899) by Herr Raethel. There is also in this volume an announcement of a new self-toning paper made by Dr. J. H. Smith, of Zurich, but I cannot find any advertisement of the British make.

Paget's self toning paper was very soon followed by others, but those that followed quickly needed a preliminary bath of sulphocyanide with or without the addition of alum; chief of these were the Ilford "Kalona" (September, 1902), Barnet (May, 1903), Wellington (June, 1903), and Imperial (1904), all of which have now given place to improved makes calling for more simple treatment. I will, however, deal with all makes in a rough chronological order, giving a brief summary of the working instructions, and what, in my opinion, are the best tones and the special features of the papers.

Paget—Collodion. Introduced July, 1901. Varieties now made: Glossy, smooth white, matt white, smooth cream and matt cream. For warm brown tones wash for 10 minutes and fix for 10 minutes in water 20 ozs., hypo 3 ozs. For colder tones use preliminary salt bath (2 ozs. to the pint) for 5 minutes, and fix in the usual hypo bath. For even colder tones use a stronger salt bath and warm up to 80 deg. F. For general work I prefer the smooth white fixed without salting, but for the most artistic effects I prefer the cream matt fixed without salting. The sepia tones are particularly rich, very even, and easy to repeat. Manipulation more simple than some papers, but variation of tones (freak tones) perhaps not so great. The Paget "Simplex" is a gelatine self-toning paper of excellent quality. It was introduced in February, 1906, and I have used large quantities of it, but I omitted it from my recent experiments being under the erroneous impression that it had been withdrawn; it is, however, still being made. Red to purple tones are easily obtainable by simply varying the strength of the hypo solution—40 per cent. for cold tones, 10 to 15 per cent. for sepia, and 2½ to 7½ per cent. for red and brown.

Imperial. The modern "Intona" gelatine self-toning paper was introduced in February, 1910, to take the place of "Kalona." The latter was put on the market in September, 1902, and it needed a sulphocyanide and alum bath before fixing. The present-day "Intona" is made in glossy mauve, carbon surface, and matt white. No preliminary washing required, fix from 5 to 10 minutes in water 20 ozs., hypo 6 ozs. Allow 1 oz. of fixing solution for each half-plate print. Excellent warm tones may be obtained on the carbon and matt surfaces by adding 20 grs. of sodium carbonate to the pint of fixing solution. I prefer the glossy paper fixed for 8 minutes in a 40 per cent. hypo solution. The tones closely approach those obtainable on P.O.P. when toned with gold in the usual way and the paper glazes well. The carbon surface is par-

B

ticularly good. In December, 1909, the Ilford Co. introduced a very good collodion self-toning paper named "Hyptona," a very popular brand, but now temporarily suspended because of the difficulty of obtaining suitable raw materials.

LETO.—This company's "Seltona" collodion self-toning paper was introduced in April, 1903, when it quickly forced its way into the front rank. It is now made in antique white and cream, matt smooth white and cream, glossy, and with tinted surfaces—cream, grey, blue and green—the latter being known as Tintona. For sepia and brown tones wash in plain water and fix in hypo 2 ozs. to the pint. For dark brown, purple and blueish tones immerse in a preliminary salt bath (2 ozs. to the pint) without previous washing, for 5 to 10 minutes, according to tone required, then fix as usual. I like best for general work the matt smooth and the antique white, both salted. For the most artistic effects I prefer the cream Tintona platinum toned, and the antique white and cream fixed without salting. An excellent all-round paper, perfect in all respects. It is, I believe, largely used with the platinum toner, and in these days of expensive platinum it may interest users of it to know that platinum-like tones may be obtained by using a saturated solution of salt in place of the usual 2 ozs. to the pint solution, and then fixing as usual. But should real platinum be preferred, in spite of its expensiveness, instructions for use are given in each packet of paper. The paper is also a good one for giving two-coloured effects, simply by the local application of the salting solution, the parts treated with salt being of a cold tone, while those touched by hypo alone become a rich brown. The most effective results—particularly in portraiture—are obtainable by this method of double toning.

RAJAR.—The Rajar "Autona" paper appeared in March or April, 1903. It is a collodion paper made in glossy, matt smooth and rough, and cream smooth and rough. For dark brown tones no preliminary washing in required; simply fix for 10 minutes in water 20 ozs., hypo 3 ozs. For light brown tones wash for 5 minutes in plain water and fix as above, but for cold tones use a salt bath (2 ozs. to the pint) before fixing. I prefer the smooth matt fixed (without first washing) in plain hypo. A very good all round paper; the glossy not being so highly glazed as most collodion papers, but, nevertheless, a good one. The paper is very easily manipulated.

BARNET.—Elliott and Sons, of Barnet, introduced a gelatine self-toning paper known as "Kiplo" in the spring of 1903, one needing a preliminary sulpho-cyanide bath. The more perfect and simple paper named "Bar-tona" was placed on the market in March, 1921. It is also a gelatine paper, glossy and matt. No preliminary washing required. Three different strengths of hypo solution are recommended for varying the tones—4, 6 and 8 ozs. to the pint—warm, "plum," and cold tones being obtainable. One ounce of solution for each half-plate print is advised, and at a temperature of 65 deg. F. The best tones, in my opinion, are those given by the glossy paper toned for 10 minutes in water 20 ozs., hypo 6 ozs. A good all-round paper and one very easy to work. The glossy paper gives very fine results from ghostly and very weak negatives, it being one of the best papers I have met with for very thin negatives.

KODAK.—The Kodak gelatine self-toning "Solio" paper appeared here in May, 1903, and is now made in glossy, matt and velvet. No preliminary washing required. Tones may be varied considerably. The ordinary simple hypo bath (3 ozs. to the pint) may be used for brown tones, or preliminary baths of sulphocyanide (20 grs to the pint), or salt (1 oz. to the pint) may be employed in colder tones. The glossy paper gives a very fine purple tone when salted, and this I prefer. The sepia tones on the matt and velvet by use of hypo alone are also particularly good. The salt bath makes a surprising difference in the tones. A good all round paper, with remarkable freedom from double tones, and one very easy to work. Takes an exceptionally good glaze. Kodak once had a good collodion self-toning paper, but this, I believe, is suspended. I used large quantities of it about ten years ago, and liked it very much. A 12½ per cent. hypo solution was used, and a large variety of tones were possible, they being governed by the usual plain hypo solutions and the salt bath, with a fixing of 10 minutes.

WELLINGTON.—A Wellington gelatine self-toning paper needing a sulpho cyanide bath was introduced in June, 1903, and a hypo only brand later. The latter required washing in plain water for 5 minutes, it was then toned in a hypo solution (6 ozs. to the pint), to which was added 30 grs. of soda bicarbonate. Fixing was carried on until the desired tone was reached, which did not take less than 8 minutes at a temperature not less than 60 deg. F. The darker the printing, and the longer the immersion, the colder the tone. Very pleasing tones were obtainable, those on glossy paper being particularly rich. The Wellington collodion paper is one of the latest, it being introduced in March, 1921. It is made in matt, glossy and cream chamois. For sepia tones wash for 3 minutes in plain water and fix in a hypo solution, 2 ozs. to the pint. For dark brown or purple tones wash as above, place in a salt solution (2 ozs. to the pint) for from 5 to 10 minutes, rinse and fix in hypo as above. The longer the immersion in the hypo solution the colder the tone, but longer than 15 minutes fixing not advisable. I like best the sepia tones on the matt paper, and the purple tones on the glossy, obtained according to the instructions. A very good all-round paper, and one specially suitable for very dense and flat negatives; it gives—when properly used—the most surprising results from faulty negatives. The tones in all cases are, I think, better if a pinch of soda bicarbonate is dissolved in the hypo solution.

IMPERIAL.—The first Imperial gelatine self-toning paper appeared in January, 1904, and it needed a preliminary sulpho-cyanide bath. The present-day make, which is more simple to use, was introduced in February, 1914. The makers supply a very carefully compiled table giving the many tones obtainable (sepia to warm purple) with various strengths of hypo, and times of immersion. No preliminary washing required. My favourite tone is obtained on the glossy paper by fixing for 10 minutes in water 20 ozs., hypo 6 ozs. Too long immersion in the fixer is apt to give a greenish tinge to the lighter tones. A good all-round paper and one easy to use, thanks to the excellent table compiled by the makers. Made in glossy and matt, the former giving a good "professional" tone and glazing beautifully.

ILLINGWORTH.—This firm's gelatine self-toning paper was introduced in the summer of 1904 under the name of "Zigo"; in 1910 the name was changed to "Enitone" for the home and Colonial trade; for European, South American and non-English-speaking countries the name "Zigo" was and is still retained. No washing before fixing. Fix in water 20 ozs., hypo 6 ozs. The longer the immersion the colder the tone, but never fix for less than 5 minutes. In my hands the best tones are obtained by fixing for 10 minutes in a slightly weaker hypo bath (5 ozs. to the pint). Never use hypo stronger than 6 ozs. to the pint. A very large variety of tones is obtainable with one strength of hypo, but difficult to get a set exactly alike unless an eye is kept on the temperature, on the strength of the bath, and time of immersion. The glossy paper gives exceptionally fine purple tones, while the sepias obtainable on the matt and satin surfaces are above the average. The paper is made in glossy, matt, and satin.

GRIFFIN.—This firm's gelatine paper, named "Goldona," was introduced in March, 1906. Originally there was only one variety, variations in tone being obtained by the use of hypo, sulphocyanide and aluminium chloride baths. The common plan of using the original "Goldona" was to immerse for 15 minutes in a 20 per cent. hypo solution for warm tones, or from 10 to 15 minutes in a 40 per cent. hypo solution for cold tones. It is now made in three varieties—green label for red or warm tones, mauve label for purple and cold tones, and brown label for sepia and brown tones; the latter is made of a matt white surface only, while the other two varieties are supplied in glossy, matt, and satin surfaces. Although so many tones are obtainable on this paper the manipulations are extremely simple. One must, however, keep closely to the makers' instructions, and be careful about depth of printing, temperature, and strength of the hypo solution. For brown and sepia tones the prints (without previous washing) are fixed in water 20 ozs., hypo 2 ozs. for 10 minutes at a temperature of 60 deg. F. For the mauve label paper (for cold tones) a stronger hypo solution (8 ozs. to the pint) is recommended. The chocolate tones obtainable on the green label (warm tone) paper are of great beauty, and show up nicely on the satin surface. It is most important to print deeply. A splendid all-round paper giving a wide range of good "professional" tones.

CRITERION.—A gelatine paper known as "Estona," introduced in May, 1906. Three surfaces, glossy matt and silky. No preliminary washing required. Fix in hypo solution, 5 or 6 ozs. to the pint, and when the desired tone is obtained rinse in slightly salted water to arrest toning action. The best results, in my opinion, are those obtainable on the silky paper by toning for 10 minutes in water 20 ozs., hypo 5 ozs. The silky surface is very pleasing, and the rich reddish brown tones most effective. This paper loses very little density during fixing. Only enough hypo solution to cover the prints should be used, as too much hypo is apt to give washed-out tones.

...—The "Yto" gelatine paper made by this firm was ... on the market in July, 1906. It is now made in several ... glossy, matt, carbon white and cream. No preliminary ... or salt baths required. Brown tones are obtained by ... in a hypo solution (4 ozs. to the pint) for from 8 to 12 ..., and at a temperature of 60 deg. F. For purple tones use ... solution 6 ozs. to the pint, and mix with the new bath an ... quantity of a once-used bath. The carbon white and the ... are excellent surfaces for all-round work, but for the most ... effects the cream carbon is my favourite—the latter toned ... brown, and the glossy and white carbon to purple. This ... is easy to use, but care must be taken to have the tempera... not below 60 deg., and not to under-print or over-tone.

...AMER.—This Belgian-made paper is a collodion made in ..., matt, and cream. It was introduced in June, 1912, and ...ended during the war, but is with us again. It is first ... for 5 minutes, then fixed for from 10 to 15 minutes in a ... of hypo, 2 ozs. to the pint, this treatment giving good ... tones. Slightly warmer tones may be obtained by using ... 1½ ozs. of hypo to the pint, and an even weaker solution has ... advocated, but is not advisable. In the weaker solution ... 1½ ozs.) fixing should not be for less than 12 minutes. For ... browns and purples use a preliminary salt bath (2 ozs. to the ...), and even this salt bath may, if desired, be dispensed with ... using a 20 per cent. solution of hypo. Fixing should never be ... longer than 15 minutes. I like best the matt paper toned in ... 20 ozs., hypo 2 ozs., for 15 minutes. A very good all-round ..., giving pleasing sepia tones.

...ch are the official instructions for using the papers, with a ... remarks of my own added. There are, at the same time, a ... general hints that may be given, as such hints apply to all ...

Always follow the makers' instructions very closely, as only by ... can one get the best results and repeat a tone. Although ... solution of any strength will give a tone—or, say, a result—... not likely to be the best the paper will produce. It is not ... to play about and ring the changes with self-toning papers ... fixing baths as one may play with plates and developers.

The final tone of the print is governed very largely by the depth ... printing, and great care is necessary if tones are to be repeated. ... papers require deeper printing than collodion, they losing ... in the hypo bath.

The hypo fixing baths must always be distinctly alkaline and ... acid. Present-day hypo is not yet quite up to the pre-war ..., and it is advisable to add a pinch of soda carbonate, ..., or a few drops of liquid ammonia to a hypo bath ... order to ensure alkalinity. Some makers wisely recommend this. ... dissatisfied with the present-day crystal hypo—some of ... I understand has been returned to makers because it refused ... fix plates—I took to using Johnson's anhydrous hypo, one part ... which equals 1½ parts of crystals.

Never leave any self-toning paper in contact with a negative for ... great length of time. It stains negatives worse than ordinary ...O.P.

Do not attempt to fix too many prints in one lot of hypo, or use ... solution than is really necessary. The best results are ... obtained—if one has the patience—by fixing each print singly in ... enough solution to cover it. Too much solution gives poor ... and washed out effects.

Glossy gelatine papers, if salted, give tones most like gold-toned ...O.P. If salting is not desired, the next best thing is to print ... and fix longer, or use a stronger hypo bath.

Four prints—gelatine glossy and matt, and collodion glossy and ...—purposely mounted with improper mountant on impure ..., showed that the gelatine matt faded the quickest: the ... collodion lasted the longest.

Most gelatine matt papers are apt to give rather muddy prints ... the negatives are not plucky. Collodion papers give the most ... prints from flat negatives.

Self-toned pictures made from mercury-ammonia intensified ... are likely to fade very quickly.

Unused papers always discolour very quickly, but such discolora... may be ignored, as it usually disappears in the hypo bath.

Always blot or wipe off superfluous water from collodion prints ... the final washing, and dry quickly in a good draught, or in ... warm room—never dry prints between blotting paper under ..., as is sometimes advised. The quicker collodion prints are ... the better they are likely to be. Slow drying under pressure ... cause markings.

Immerse all self-toning papers in hypo or salt solutions evenly, quickly and thoroughly, so as to ensure even tones. Parts allowed to get behind in the toning will never catch up.

Two collodion postcards, glossy and matt, printed in 1903, have been hanging exposed to smoke, gas, and chemical fumes for eighteen years. The glossy picture has faded badly, but the matt picture remains as perfect as when made. Glossy collodions in an album faded before the matt surfaces, though made at the same time and given the same treatment.

All things being equal, glossy gelatines are the "trickiest" to work and to repeat tones; matt collodion the easiest.

Unless makers advise to the contrary a hypo bath of a temperature between 60 and 65 deg. F. will be found to give the best results.

Salt for salt baths should be of the common or kitchen variety, not specially prepared table salts, some of the latter are most unsuitable. Be particularly careful to note whether the paper is to be washed in plain water before immersing in the hypo bath, this washing or non-washing is important.

Thoroughly fixing is essential if permanency is a consideration. If a fixing bath lightens a print too much, simply print deeper to allow for the reduction. Some gelatine papers need very deep printing.

If a purple or a dark brown tone is aimed at and cannot be secured—the tones being too red—the defect is probably due to powdery hypo crystals, indicating the presence of soda sulphite, which prevents toning. If hypo crystals are covered with powder, wash off the latter before weighing out and dissolving.

Efforts to "help" toning by adding a drop or two of gold chloride solution to the hypo bath have not been found satisfactory. The most curious results have been obtained. If the papers are properly used such "help" is not required, even if it were possible.

The complaint one hears the most frequently about collodion papers is that of curling during manipulation. This defect may be minimised—in some cases entirely overcome—by not putting more than half-an-inch of water, salt or hypo solution, when first wetting the dry print, and putting the latter in face downwards. Once the pictures are wetted there will be little or no tendency to curl.

If the lighter tones of a gelatine picture are greenish it is a sign of over-fixing or the use of an old hypo solution; if the tones are too red either the fixing bath is too weak, or the prints have not been in it long enough.

Cracked or scalded collodion prints are caused by too quick or rough washing, and allowing them to double up and crease when in the solutions or washing water.

P. R. SALMON.

FORTHCOMING EXHIBITIONS.

December 3 to 17.—Scottish Photographic Circle. Hon. Secretary, W. S. Crocket, 10, Parkgrove Terrace, Tollcross, Glasgow.

1922.

January 21 to February 4.—Partick Camera Club. Particulars from the Hon. Secretary, James Whyte, 51a, Peel Street, Partick, Glasgow.

February 11 to 25.—Scottish Photographic Salon. Particulars from the Secretary, James F. Smellie, Braefindon, Allanshaw Street, Hamilton.

February 14 to 17.—Exeter Camera Club. Latest date for entries, January 30. Particulars from C. Beauchamp Hall, Hon. Exhibition Secretary, Exeter Camera Club, "St. Denys," Bellevue Road, Exmouth.

A CONTINENTAL PHOTOGRAPHIC DIRECTORY.—Our confrère, M. Paul Montel, of "La Revue Française de Photographie," has in preparation a directory of photographers and photographic dealers and manufacturers in France, Belgium and Switzerland, which is to be issued in February next as "L'Indicateur de l'Industrie Photographique." The volume will also contain a list of trade marks and names relating to photographic goods. Entries, both free and to be paid for, may be inserted in the volume, the latter according to a tariff obtainable on application to M. Montel, 35, Boulevard St. Jacques, Paris XIVe.

Patent News.

Process patents—applications and specifications—are treated in "Photo-Mechanical Notes."

Applications, November 21 to 26 :—

COLOUR PICTURES.—No. 31,406. Process for converting silver prints into colour pictures. Akt.-Ges. für Anilin-Fabrikation.

CUTTING DEVICE.—No. 31,512. Device for composing and clamping photographic prints, etc., for cutting circles, etc. A. E. E. Barneveld.

CAMERAS.—No. 31,017. Photographic cameras. R. Longbottom.

FOCAL-PLANE SHUTTERS.—No. 31,441. Focal-plane shutters for photographic cameras. A. G. Pickard and Thornton-Pickard Manufacturing Co., Ltd.

CINEMATOGRAPHY.—No. 31,723. Cinématograph film. F. N. Cowdy.

COMPLETE SPECIFICATIONS ACCEPTED.

These specifications are obtainable, price 1s. each, post free, from the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C.

The date in brackets is that of application in this country; or abroad, in the case of patents granted under the International Convention.

FOLDING CAMERAS.—No. 171,024. (October 6, 1920.)—The object of the invention is to produce a camera which, when folded, is (having regard to its capacity when open for use) abnormally thin and hence more portable. The result is secured by special and new arrangement of the struts of the lens front. These struts are connected at the upper ends to the sides of the lens front by pivot hinges, and at the other ends or feet are preferably connected together by a cross rod. They can swing on the pivot hinges on the sides of the front so that if turned upwards the rods will lie approximately along the sides of, and the cross rod (if any) above, the lens front, and when turned down they will come into the required position on the opened front of the camera to give support to the carrier. On the lower ends or feet the struts travel in guides on the front of the camera so that the closing or opening of the front of the camera lifts the rods to the upturned position, or brings them down to the supporting position. Hinged to the bottom of the lens front is a flat metal member, which also slides in guides (preferably the aforesaid guides) in the front of the camera, and which determines the

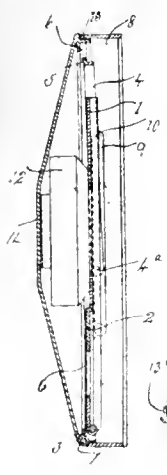

Fig. 1.

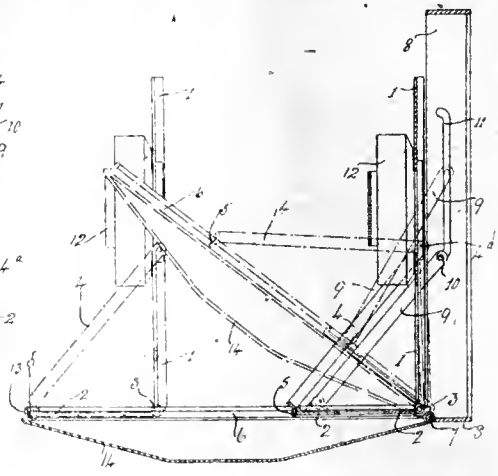

Fig. 2.

position of the struts in relation to the lens front when arranged for use. This member always slides in and follows the plane of the guides, when the camera is open lying along the front, and folding up with the front when the camera is closed. The struts, when the camera is open and the lens front pulled forward ready for use, are rigidly clamped in the required position by being held between a stop and the flat metal member.

By means of this arrangement the lens front, together with its struts, when the camera is closed, only takes up space corresponding to the thickness of the lens-front itself. This admits of a reduction of the structural depth of the camera itself, inasmuch as space need only be provided further in the front of the camera for the lens and its attendant apparatus, and the required space for this is secured by making the front of the camera bowl shaped, producing a very suitable outside shape of the camera to fit easily into a pocket.

In the drawings an example of the invention is shown. Fig. 1 is a section of the closed camera, Fig. 2 a lateral elevation and part section of the open camera in various positions.

The lens front 1 is connected by a pin joint 3 with the flat metal member 2, which is mounted in a slide guide 6 in the front. The lens-front struts 4 are connected by pin joints 4a to the sides of the lens front, and the feet 5 of the struts rest in the slide guide 6, which is provided with a stop 13. The front 14 (of bowl shape) is connected by means of the joint 7 with the camera body 8. The struts 9 (which are of usual design) rest with their free ends 10 in slide guides 11.

The mode of operation of the arrangement is briefly as follows :—

On opening the camera (fig. 2 dotted lines) first of all the front 14 with the guides 6 turning on the pivot 7 assume the position in relation to the camera case shown in fig. 2, the stay 9 moving at its free end 10 in the guide 11 and determining such position and holding the front and the guides 6 rigid in relation to the body 8 and the guides 6 at right angles to the lens front.

The movement of the slide 6 causes the flat member 2 (which moves in the slide 6) to move on its pivot 3 to the position shown in fig. 2, and at the same time causes the stay 4 moving on its pivot 4 to assume the position shown in fig. 2, the feet 5 of the struts 4 sliding back in the guide 6 until they strike against the flat member 2.

If then the lens front 1 is drawn out of the camera body, the flat member 2 slips forward in the guide 6 and pushes in front of it the cross rod and the feet 5 of the steadying rods 4 until the feet and cross rod strike against the stop 13. In this final position (fig. 2, double dash lines) the feet 5 are clamped fast between the flat member 2 and the stop 13, and the camera is ready for use.

On folding up the camera the lens front is first of all pushed back and the front 14 then moved upwards. Then, as may be seen from the drawing, the feet 5 slip in their guides and in this way come to lie at the side of the upper part of the lens front when the camera is folded, while the flat member is folded up into the vertical position as shown in fig. 1.

The bowl-shape form of the front 14, as already mentioned, is made possible by this arrangement of struts, and, as shown by the drawing, it presents a camera corresponding to the cross-section of a pocket.—Bruno Leonard Lion, 18, Ashbourne Avenue, London, N.W.1, for Paul Guthe, Dresden.

COPPER MORDANT DYE TONING.—No. 163,337. (December 3, 1918.) The invention relates to a modification of that described in Patent No. 147,005. ("B. J.," June 3, 1921, p. 328, and "Colour Photography" Supplement, June 3, 1921, p. 23.)

In the usual copper toning the silver picture is converted into a copper image by using about equal parts of solutions of copper sulphate and potassium ferri-cyanide of 10 per cent. strength and about 10 times the weight of either of potassium citrate. Such a bath consists, for example, of 15 parts of copper sulphate, 115 parts of potassium citrate, and 13 parts of potassium ferricyanide, all in solution of 10 per cent. strength. The picture obtained after dyeing is particularly suitable for viewing by daylight and for portraits, because, in consequence of a more or less strong turbidity and opacity of the deposit, the picture has an enhanced artistic value.

For projection transparencies, however, a matt picture is not always suitable. By the improvement of this invention pictures are obtained which are highly transparent and appear on the screen in brightest possible colour. The improvement consists in using both the copper compound and the potassium ferricyanide solution in substantially smaller proportion than in the usual toning bath, while retaining the normal proportion of potassium citrate. The proportion of copper compound and potassium ferricyanide is reduced to from $\frac{1}{4}$ to $\frac{1}{3}$ of the usual proportion, but may not amount to half the usual proportion. The picture obtained with such a toning bath appears quite different from that obtained with the normal bath. It has a varnished appearance, although no varnish has been used, and is very transparent, with powerful colour effect. Its production follows the usual lines.

The transparency of the coloured copper picture can be still

further increased, so that it cannot be distinguished from a pure dyestuff picture, by using more potassium ferricyanide than copper, the foregoing limits being observed.—Dr. Arthur Traube, 12, Rauchstrasse, Munich.

The following complete specifications are open to public inspection before acceptance :—

FINDERS.—No. 171,695. Finders for photographic apparatus. G. Arndt.

Trade Names and Marks.

APPLICATIONS FOR REGISTRATION.

CORADON.—No. 419,165. Chemical preparations for photographic purposes and photographic films. Farbenfabriken vorm. Friedr. Bayer & Co., Leverkusen, near Cologne-on-the-Rhine, Germany, manufacturers October 4, 1921.

FILMDEX.—No. 418,354. Philosophical instruments, scientific instruments and apparatus for teaching. André Louis Stouvenaut, Royston, Portsmouth Road, Thames Ditton, Surrey, cinematographer; and Hedley Frank Glover Smith, 6, Stanley Gardens, Cricklewood, London N.W.2, cinematographer September 6, 1921.

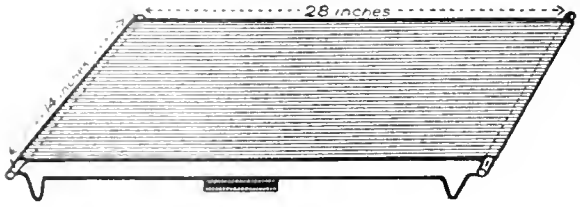
KATANOL.—No. 419,040. Chemical substances used in manufactures, photography or philosophical research and anti-corrosives. Farbenfabriken vorm. Friedr. Bayer & Co., Leverkusen, near Cologne-on-the-Rhine, Germany, manufacturers September 30, 1921.

M.S. (DEVICE.)—No. 419,470. Chemical substances used in manufactures, photography or philosophical research and anti-corrosives. Murphy & Son, Ltd., "The Cedars," Sheen Lane, Mortlake, London, S.W.14, technical chemists. October 12, 1921

New Apparatus.

ENSIGN PLATE GRIPS.—Messrs. Houghtons, Ltd., 88/89 High Holborn, London, W.C.1, have just introduced a wire holder or grip for negatives, which allows of the negative being hung from a line, or any narrow rod, when drying or being washed. The drawing clearly shows the form of this little accessory, which is an exceedingly good and practical device. The spring grip is made of stout galvanised wire, provided with a rubber covering at the two places (shown black in the drawing) where it comes in contact with the opposite edges of the negative. The spring of the wire, in conjunction with the friction of the rubber, thus gives a firm hold of the negative. There is a very great deal to be said for suspending negatives in this way when drying. When using the ordinary drying racks access of air to the gelatine surfaces is extremely restricted, whilst by standing negatives on a shelf to dry there is ample opportunity for dust to creep on to the emulsion film, and in any case the edge of the negative on which the latter rests is a very long time in becoming perfectly dry. Moreover, the clips allow of negatives being suspended in a vessel of water for washing, in which circumstances an ample current of water can be brought in contact with them. The grips are supplied in five sizes, at the following prices per packet of 12 :—3½ x 2½ inch 2s. 6d.; quarter-plate, 3s.; postcard, 3s 6d.; half-plate, 4s.; and whole-plate, 5s.

A COLLAPSIBLE DRYING FRAME.—Messrs. Houghtons send us a collapsible drying frame just placed upon the market by them for the convenience of amateur makers of prints. As shown in the diagram the frame consists of two pairs of stiff wire struts, each of which forms a side support for a length of muslin attached to a pair of wooden rollers. The two elements of each pair of supports are united by thrusting them into a short length of bent iron plate, seen midway in the diagram. When fully extended the area available for the laying down of prints is 28 x 14 inches, whilst, when folded, the device packs loosely into an envelope measuring 15 x 4 inches.



New Materials.

PRINT-FINISHING PENCILS.—Messrs. Jonathan Fallowfield send us a set of pencils, specially prepared for retouching of matt or satin surface prints in black, brown, grey or sepia. The pencils provide a ready means of spotting and touching prints of a considerable range of colours; in fact, among the four colours of lead which are provided it will be found that any print which is produced in the ordinary way can be satisfactorily matched. The pencils are supplied at the retail price of 6d. each, or 5s. 6d. per dozen.

ROYAL PHOTOGRAPHIC SOCIETY.

Meeting held Tuesday, December 6, the president, Dr. G. H. Rodman, in the chair.

Mr. Howard M. Edmunds delivered a lecture on a new mode of producing sculptures by means of photography. The opto-mathematical principles of the process which he had invented are by no means easy of explanation, even with the aid of blackboard diagrams and lantern illustrations. The patent specification published last week provides an outline of the method, which consists in projecting upon the face of the sitter a fine spiral pattern and photographing the sitter so illuminated under optical conditions such that the admission node of the camera lens is in the emergent nodal plane of the projection lens. In these circumstances a negative is obtained in which deformation of the spiral design is a measure of the degree of relief in the spatial object photographed. A print from the negative forms the means of controlling, through a visual manual adjustment, the operation of a fine high-speed drill working in the material to be carved. It is caused to rotate slowly, a microscope mounted vertically above it being constantly moved, so as to keep its cross-threads continuously upon the continuous spiral line. The microscope is mounted upon a mechanical system by which its movements are conveyed to a drill working to and fro perpendicularly to the material to be carved. Such, in very rough outline, is the process which Mr. Edmunds has developed with great mathematical and mechanical ingenuity. His description naturally evoked a great many questions, which were answered by Mr. Edmunds, to whom, on the proposition of the chairman, the hearty thanks of the meeting were accorded.

LANCASHIRE SOCIETY OF MASTER PHOTOGRAPHERS.

The first ordinary meeting of the committee appointed under the reorganisation scheme was held at the Society's office, 39, Blackfriars Street, Manchester, on Wednesday, November 30. There was a large attendance of members, and the meeting was presided over by Mr. Arthur Winter, the president, who was congratulated by those present on his recent wedding.

The hon. treasurer submitted his statement, and in doing so informed the committee that a large number of members had not taken the trouble to reply to his communications. After a very lengthy discussion on this point, it was unanimously decided that the president be asked to send a final letter to these members, pointing out to them the expense incurred by the numerous applications for the payment of subscriptions, and asking that they should definitely state if it was their intention to remain members of the Society or not. In the event of no reply being received to the president's letter, the secretary was instructed to write and ask for the return of the certificate of membership.

A lengthy discussion then took place on the programme for next year, and it was decided to hold a general meeting in Manchester early in January, and to arrange for a practical demonstration to be held at one of the studios in the centre of the city, so as to demonstrate the advantages or otherwise of films as against plates. It is intended to make this demonstration a thoroughly practical one, and it is hoped that every member will take the advantage of attending.

Another demonstration of a practical nature will be held in March, and the secretary was instructed to get in communication with the Autotype Company, of London, and to ask them to arrange to give a demonstration of their "Carbro" process, and it was also suggested that a demonstration of aerograph work be also given

The secretary reported that there was a movement on foot to organise a trade exhibition and conference to be held at Blackpool during May next; it being suggested that the photographic and the cinematographic trades co-operate in this effort.

After some discussion the committee decided to give this project their whole-hearted support, and the secretary was instructed to make the arrangements for the annual meeting of the Society to be held during the week of the exhibition and conference, and the committee was asked by the president to endeavour to arrange for some practical demonstration to be given during that week.

Before separating, an opinion was expressed that this was one of the most successful meetings that had been held since the incorporation of the Society, and it was felt that during the coming year the paying members of the Society would take a greater interest in the work of the Society and attend the meetings more regularly.

Commercial & Legal Intelligence.

LEGAL NOTICES.—Notice of intended dividend is given in the case of Archibald Rouse, picture frame maker and dealer, residing at 21, Kingston Road, Freemantle, Southampton, and carrying on business at 5, Queen Anne's Buildings, Canal Walk, Southampton, under the style of Godfrey and Company. Proofs must be lodged on or before December 14, with Frederick William Darley, Official Receiver, Midland Bank Chambers, High Street, Southampton.

NEW COMPANIES.

EDMUNDS CAMEOGRAPH CO., LTD.—This private company was registered on November 23 with a capital of £25,000 in 24,925 participating preference shares of £1 each and 1,500 ordinary shares of 1s. each. Objects: To adopt an agreement with H. M. Edmunds and to carry on the business of photo-sculptors, photographers, sculptors, engravers, printers, engineers, makers of lenses and cameras, manufacturers of and dealers in works of art of all kinds, etc. The subscribers (each with 250 ordinary shares) are: H. Edmunds, M.I.C.E., Moulsecombe Place, Brighton; J. G. S. Gibson, F.R.I.B.A., 5, Old Bond Street, W.1; H. M. Edmunds, A.M.I.C.E., Moulsecombe Place, Brighton; J. D. Forsyth, 51, Broadhurst Gardens, Hampstead, N.W.6, artist. The subscribers are to appoint the first directors. Secretary: E. J. Pilcher. Registered office: Parliament Mansions, Victoria, S.W.

NEWTON, ROBERTS & CO., LTD.—This private company was registered on November 24 with a capital of £2,000 in £1 shares. Objects: To acquire the business carried on at 40, Great Pulteney Street, W., as "C. E. Newton," to adopt an agreement with J. A. Watts, C. E. Thirkettle and Mabel Watts, and to carry on the business of manufacturing photographic apparatus and chemical, optical, scientific instruments, etc. The subscribers (each with one share) are: A. Rothery, 12, Montana Road, Tooting Bec, S.W.17, accountant; J. A. Watts, 51, Downhills Park Road, Philip Lane, Tottenham, camera maker; W. G. Roberts, 5, Nelson Terrace, N.1, instrument maker. The directors are to be appointed by the subscribers. Qualification (except first directors), £100.

GLASGOW AND WEST OF SCOTLAND SOCIETY OF PROFESSIONAL PHOTOGRAPHERS.—At the next meeting of the Society, to be held on December 13, in the Glasgow School of Art, a lecture on psychology in the studio will be given by Mr. C. P. Crowther.

News and Notes.

ROYAL PHOTOGRAPHIC SOCIETY.—At the meeting arranged by the Scientific and Technical Group for Tuesday next, December 13, Mr. G. I. Higson will read a paper on potassium persulphate as a reducer, and Mr. F. C. Toy will describe an improvement in the Goldberg wedge. A paper by Dr. S. E. Sheppard on the action of halides and cyanides on the photographic emulsion will also be read.

SECONDHAND REFLEX CAMERAS.—The City Sale and Exchange, 93½, Fleet Street, London, E.C.4, send us a special clearance list of over 200 reflex and folding focal plane cameras, which are being offered from this depôt of the firm. The list includes cameras of almost all makes and sizes, and contains particulars of many reflexes of that most advisable size for the amateur, namely, 3½ x 2½ ins. A copy of the list is obtainable free on application.

POSTCARD PRINTING.—The London & Provincial Photographic Service, of 18, London Road, Leicester, send us some samples of their work in black and sepia matt and semi-matt cards, which are altogether excellent. The firm are making a specialty of only first-class work, at the lowest prices, as set out therewith, and from a specimen of the order form which is sent to us evidently carries on its business in a well organised manner. No extra charges are made for vignetting, toning or half-tone orders.

THE ABDULLA ALMANACK for 1922 is just being issued by the well-known cigarette firm, of 173, New Bond Street, London, W.1, to the number of 10,000 copies, at the price of 1s. 6d. The gross receipts are being devoted to the British Red Cross Society, Messrs. Abdulla bearing the expenses of production. The Almanack is of attractive design for wall use, and consists of reproductions in colour of works by well-known artists, representing aspects of national life in the different countries of the world. These have been drawn specially for the publication.

ECLIPSE PHOTOGRAPHS TO PROVE EINSTEIN'S THEORY.—The photographs to be taken in Australia during the eclipse of the sun next September are expected to put the much-talked-of Einstein's Relativity theory to the supreme test, and astronomers of South Australia have sent British scientists an invitation to journey out to the colony to observe the total eclipse. It is pointed out that if the stars close to the sun appear in a different position during an eclipse than when the sun has moved away from their neighbourhood, and if the displacement is of the magnitude predicted by Einstein, his theory will emerge triumphant.

KODAK SHOWCARDS for the Christmas season have been produced for the use of dealers in most attractive styles. They are three in number, all fine examples of colour printing. One by Lawson Wood is a fantastic version of Father Christmas putting a Kodak into a super-stocking hung by the fireside. The title of another, "Daddy, how did you know," delightfully emphasises the choice of a camera as a Christmas gift. In the third the Kodak girl, still summer clad, is taking a snapshot of a skating party at Mürren or Grindelwald, elevation apparently 15,000 ft. But all are most effective as posters, and will be welcomed by dealers in the Kodak manufactures throughout the country.

CROYDON CAMERA CLUB.—The annual dinner of the club was held at the Greyhound Hotel, High Street, Croydon, on November 30 last, Mr. J. Keane, president of the club, in the chair. Croydon is nothing if not hospitable, and a number of guests had accepted the club's invitation, among them Dr. H. Rodman, and Messrs. J. C. Weston, Arthur C. Brookes, F. C. Tuney, W. L. F. Wastell, and George E. Brown. In a vein of dry humour, the president proposed the only toast of the evening—the guests of the Club, to which Dr. Rodman and Mr. Brown replied. A most enjoyable evening followed, to which Mr. Tuney, Mr. Harpur, and Mr. Ackroyd contributed songs, and Mr. Wastell anecdotes. Dr. Knott and his daughter, Mrs. Carpenter, gave an extraordinary demonstration of thought-reading, and Mr. C. Keeler repeated, with variations, his performance of last year, in which, as Father Christmas, he distributed to many members presents appropriate to their personal failings or grievances. The proceedings of a happy company lasted until a late hour, having been enlivened by a stream of informal and spasmodic fun in accordance with the best and most sacred traditions of the Club.

FOREIGN PHOTOGRAPHIC LENSES.

To the Editors.

Gentlemen.—My experience has been all against the foreign article. I had a Goerz lens which could not be used without a long lens hood, however poor the light.

Another German lens, with an aperture marked *f*/6.5, worked at *f*/9.

I recently purchased a soft-focus lens from America. The lens was praised sky-high in the firm's catalogue. Beautiful reproductions of photographs taken with the lens were given, and an actual reproduction of the lens, showing it as a beautifully finished doublet. When the lens arrived (24 dollars for 6¾-in. focus) it was a single lens in a badly finished mount.

When I pointed out the difference between the illustration of the lens in their catalogue and the actual article, they simply said that the illustration was an optical delusion.

No more Yankee or Boche goods for me.—Yours faithfully,

"KEATINGS."

To the Editors

Gentlemen.—The correspondence on this subject only serves to demonstrate, in my opinion, the complete dependence of most of us who use lenses upon what the makers may feel inclined to tell us about them; or, should we desire confirmation of such statements we have no option but to send the lenses to the National Physical Laboratory, and to pay a fee for information which may not convey a great deal to us when translated into terms of practical commercial photography.

My object in writing this is by no means to cast any insinuation against any manufacturer, for I am convinced that modern lenses are much more wonderful tools than most photographers imagine, but to suggest that there is great need among us for instruction or information regarding lenses which goes beyond the elementary details of relative aperture, depth-of-focus tables, and so on, but stops short of the "scientific" or theoretical side which interests the lens-maker but not the user.

It must be as obvious that a photographer has as little need (as he has as little time) to study optics for the purpose of understanding his lenses as he has need or time for learning chemistry and emulsion-making in order to know how to use various kinds of plates to the best advantage in the hundred-and-one problems that fall to the lot of the commercial operator. The qualities of our lenses in solving these problems one can really only learn by trial and error, and one gets to prize a certain lens because of a certain job that it did so well. One often notices that an operator, on setting up in business for himself, seeks a lens identical with the one that he has been used to for so many years, though probably there are plenty of others whose results would be indistinguishable or better. He mistrusts others because he has no ready means or knowledge for testing any other lens, and knows equally that the average photographer's test, that of making a couple of negatives with it under normal (that is to say favourable) conditions, is no indication of the qualities a lens may or may not possess for getting a result under difficulties.

The ordinary test which anyone can apply, that of photographing a sheet of newspaper at open aperture, does not by a very long way cover the information that one would desire, and one supposes that all tests made in factory or laboratory are refinements of this type of test. There are, however, so many occasions on which a lens is used *not* with its axis centrally perpendicular to the plate. In fact, it would be hardly an exaggeration to say that the vast majority of exposures made by the professional do not comply with that condition, and frequently one employs purposely a lens in ways which a lens manufacturer would probably

be horrified at. For instance, I very often use a certain whole-plate lens with the back of the camera vertical and the lens not only two inches or more below the centre, but also swung downwards and sideways. Needless to say, the stop employed is a very small one, but the part of the image in which particularly good definition and great depth of focus are required lies somewhere in the margin of a 15-in. circle. A half-plate lens by the same maker becomes, when slightly stopped down, a better wide-angle than some specially made for the purpose, but has the peculiarity, when employed for enlarging, or for lantern-slide reductions, of requiring the most accurate focussing and shows considerable want of definition when the front is swung so slightly that with other lenses the difference is scarcely noticeable. I have to produce acute sharpness of detail, and so may be hypercritical in criticising the performance of various lenses.

At the same time such exacting requirements make one appreciate what a good instrument really will do in extraordinary circumstances, and with one exception the lenses that I have most satisfaction from are of British manufacture. My point is that I have no knowledge of why these various lenses behave in unexpected ways when problems arise. Manufacturers, as a rule, are not very communicative. For instance, one firm issues a lens of which the smallest aperture is *f*/22. They state as a reason that this lens works at its best at that aperture, but as one often has need to stop down even beyond *f*/70 (at which stop another authority states that definition is worsened) one is left in bewilderment as to what will happen if one uses a lens of the same series by the same maker which is actually graduated to *f*/64.—Yours faithfully,

D. Charles.

INVENTIONS IN COLOUR PHOTOGRAPHY.

To the Editors.

Gentlemen,—I have read with interest Mr F. E. Ives' observations on the work of all and sundry who have laboured in the realm of colour photography.

Since my student days in Philadelphia I have read much which has been published by my eminent fellow townsmen.

I have also had the privilege of from time to time examining some of Mr. Ives' colour photographs.

But were Mr. Ives' most ardent admirer to devote the necessary time to examine all he has invented, patented and claimed, I fear there would be little or no time left from Nature's average allowance to permit of original research or the creation of methods to which Mr. Ives might not lay claim. Speaking for myself only and with due diffidence, I am not prepared to acknowledge so liberal a measure of sole proprietorship in colour photographic processes as Mr. Ives is prone to assume.

Mr. Ives' reflector-filter, of which I have heard but which I have never seen, may, or may not, have been the first suggested. This does not seem to me to matter. I do venture to assert, however, that the combination of a reflector-filter, constructed to a carefully computed curvature (for which computation I expressed my obligation to Prof. A. E. Conrady by joining him with myself in the patent) with devices for keeping such curvature constant, and for moving plates which are to be exposed at right angles to each other, so as to assure their always being in the same focal plane, was the first really accurate means of securing simultaneously exposed tri-colour selection negatives. It is obvious that, lacking any of these elements, there would be little of value in the others.

This was the Polychromide camera, patent No 28,722 (1912), applied for in 1911 and granted me in the U.S.A. Great Britain, Germany, France, Switzerland, Belgium, etc., etc.

I still have the temerity to believe that this camera remains the simplest and most efficient one-lens one-filter device which has been constructed, and that until its advent negatives in perfect register were not obtainable. I say this in the face of a deluge of patents and claims to priority by Mr. F. E. Ives. Its recent adaptation to cinematography (with success) has, I fear, been the cause of its seeming neglect by its still fond parent. The recent completion of a quite simple method of making paper prints from Polychromide negatives (where again I fear I am under no obligation to Mr. Ives) will, I anticipate, be the means of its early being given a dusting in anticipation of early commercial exploitation.

In closing my remarks, may I "start something" by observing that it has often occurred to me that we have all been losing something while we have been wasting much valuable time in what seems (to me) to be utterly futile dependence upon so-called panchromatic emulsions? At the risks of exposing my devoted head to the storm, I venture to prophesy that the road to success in colour photography will before long be found to lie in the direction of differentiated sensitisation of plates or films which are to be used for colour separation. The resultant elimination of filters and screens, with the consequent gain in speed and accuracy of selection, will ultimately consign all special cameras to the scrap heap or the museum. It is also more than probable that methods of making colour prints and transparencies will be considerably revised when the numerous and more or less uncertain dyeing, toning and colouring processes in general use are brought a little closer to those used on Nature's own palette. I predict that this will be found more simple than heretofore supposed, but I am becoming indiscreet! For I, too, have contracted the patent habit —Faithfully yours,

Aron Hamaurger.

CONTRASTY TRANSFER BROMIDE PAPER FOR COPYING.

To the Editors.

Gentlemen,—In reference to the short article, "Multiple Negatives for Photo-Lithography," by Mr. W. T. Wilkinson, in your issue of December 2, p. 716, we should like to draw attention to the fact that we supply a special contrasty Transferotype paper which, when used according to the special procedure which we recommend, is a much more suitable material for copying work than the ordinary and more rapid Transferotype paper. We have nothing to say against the usefulness of the ordinary paper in the making of copy negatives of natural full-tone subjects, but for work in which the utmost degree of contrast is required, as in process work, the ordinary paper is by no means an efficient substitute for the wet collodion plate.

On the other hand, we claim that by means of our paper, which is solely made by the Kodak Co. for us, we can obtain beautifully crisp images, and we should be very pleased to show you, or anyone who cares to call on us, the very fine results made in this way, or shall be very pleased to send anyone our special printed instructions. The process is so simple that anyone doing this work is assured of success. The process is particularly applicable to the making of negatives for copies of fine line originals, or, in fact, for any work where a wet plate negative would be used.—Yours faithfully,

per pro Pictorial Machinery Ltd.,
Frederic T. Corkett,
Managing Director.

7, Farringdon Road, London, E.C.1,
December 5.

[We note in the working instructions referred to by Mr. Corkett for the use of the paper which is supplied as "Pictograph" that the paper is supplied in eight sizes, from 4½ x 3⅛ inches to 59 x 39 inches, the papers being cut somewhat smaller than the regular sizes of negatives in order to allow for cleaned-off negatives to be used as supports after transfer, the paper stretching very slightly when wetted.—Eds., "B.J."]

Take a number of sheets of glass corresponding with the negative required and coat same with a substratum of:—Hot water, 100 ozs.; gelatine (Nelson's), 4 ozs.; chrome alum, 100 grains.

In adding the chrome alum it is advisable to dissolve the latter in part of the hot water and to add this hot solution to the hot gelatine solution drop by drop, with constant stirring.

Set glasses up to dry, or the plates can be dried at once over a gas ring.

A good method is to coat over night a quantity of the glass, thus having next day a supply ready for immediate use. The object of this substratum is the holding of the sensitive film to its glass support.

Take some of the sensitive paper and immerse for a few minutes in a tray of cold water, then squeegee on to the substratumed sheets of glass.

The paper so treated can then be exposed in the camera either while it is wet, or it can be allowed to dry and exposure then made. The exposure is made through the glass, and consequently the back of glass should be clean. A reversed negative can be thus made direct.

If the exposure has been made while the paper is in a moist state, it is preferable to allow the paper on the plate to dry before development. When dry, the paper on its glass support is placed in hot water rather hotter than the hand can bear (150 deg.). After a few minutes in this hot water bath, the paper will be found to strip off easily, thus leaving the sensitive exposed film upon the glass ready for development. Now place the plate in cold water, making sure the film is free from any of the medium used (the soluble adhesive solution whereby the emulsion had been temporarily affixed in its manufacture to the paper), when the plate is ready for development.

This can be done by any good formula, but developer as follows is found to give excellent results:—

(*a*) Hydroquinone	...	1 oz.
Potassium bromide	...	1 oz.
Potassium metabisulphite	...	1 oz.
Water	...	40 ozs.
(*b*) Caustic potash	...	2 ozs.
Water	...	40 ozs.

For use take equal parts (*a*) and (*b*).

Fix in a bath of hypo, 4 ozs.; water, 40 ozs.

After fixing, wash in running water for five minutes. A further bath for a few minutes in a solution of Pictograph hypo destroyer will ensure a negative free from all traces of the fixing bath.

If negative is in any way stained or fogged it can be much improved and rendered bright and clear by placing in Pictograph Clearing Solution. This excellent clearing solution will not do its best unless all trace of fixing solution has been removed from the negative.

Intensification, if necessary, by any of the usual methods known may be employed as preferred by the operator.

The above method of negative production provides a cheap and reliable means of making negatives for process workers. The negative produced is crisp, clean, and remarkably free from defects, and requires less spotting and after-attention than the average wet plate. As a reversed negative is obtained direct, good clear glass should be used. The substratum advised may be dispensed with; it is a precautionary measure, but is not a necessity.

THE 1922 CONGRESS OF THE PROFESSIONAL PHOTOGRAPHERS' ASSOCIATION.

To the Editors.

Gentlemen,—At a meeting of the Congress Committee appointed by the P.P.A. Council it was decided to hold an independent Congress, and to celebrate the 21st year of the Association's foundation, in the month of September next, at the Princes Galleries, Piccadilly, W.

The galleries selected for the purpose are among the best and most convenient in London—very central and spacious—affording special facilities for a large display of professional photography. In addition to the "home" collection of pictures, it has been decided to invite exhibits from the most prominent professional photographers residing abroad, and it is hoped this departure will prove an attraction and education.

In the past the educational programme has been cramped for lack of accommodation, but as the Princes Galleries will be entirely under the control of the Council, it will be possible to arrange a more extended list of lectures and demonstrations.

The position and interior comfort of the Galleries afford exceptional opportunities for extending the social side of the Congress, and it is determined to take full advantage of it.

The reason the foregoing information has not been made public earlier, was because Mr. Brookes desired to make the first announcement, and our Council—in consideration of the many happy associations with him at the Royal Horticultural Hall—agreed.

Fuller particulars will be issued to members of the Association as soon as possible.—Yours faithfully,

LANG SIMS,
Secretary.

437, Brixton Road, S.W.9.
December 6

Answers to Correspondents.

In accordance with our present practice a relatively small space is allotted in each issue to replies to correspondents.

We will answer by post if stamped and addressed envelope is enclosed for reply; 5-cent International Coupon, from readers abroad.

Queries to be answered in the Friday's "Journal" must reach us not later than Tuesday (posted Monday), and should be addressed to the Editors.

J. W.—You should write to the Registrar of Trade Names and Designs, 25, Southampton Buildings, Chancery Lane, London, W.C.2, for a circular of instructions in registering a trade mark or design.

T. S.—The copyright is yours. You should point out the fact to the proprietors of the paper which has now printed it, asking them what they propose to do in the matter. You should take this course in preference to naming any particular sum in respect to the infringement.

V. B.—Ordinary distemper or size colour is generally used for backgrounds. It is better to purchase one of the ready-made brands. The foreground may be distempered first and then given two thin coats of good white oil paint, this allows footmarks to be sponged off.

E. V.—Registration at Stationers' Hall was abolished when the present Copyright Act came into force in June, 1912. You can take action for infringement of your photograph, since the Act assumes that you are the owner of the copyright, unless the defendants can prove otherwise.

H. J.—Your trouble is probably due to allowing your sheets to become too dry before cutting. It is usual to keep the sheets in a hydraulic or powerful screw press for some hours, say overnight, then to cut two edges true, one sheet at a time, with an ordinary card cutter. They are then "knocked up" level and cut in the guillotine. This is the usual practice of the big postcard printers.

A. C.—We confess we are at a loss to account for the disappearance of the image in the acetic acid bath. We do not think its disappearance has been caused by the use of the sulphocyanide or the ammonia. We think there must be some original image there, even if invisible. This might be redeveloped with the Wellington silver intensifier, formula for which is given in the "Almanac."

S. A.—We have found the most generally useful installation to be six 1,000 c.p. half-watt lamps. You can, of course, use fewer lamps of higher candle-power, say, two 3,000, but the light is then not so well diffused. The lamps should go up to 8 ft. from floor for standing figures and groups, and should come down to about 5 ft. for children and sitting figures, as this greatly shortens the exposure.

K. W.—We do not know of any enamel now on the market that will fulfil your requirements, as our manufacturers almost invariably stove their work. There was, before the war, a German enamel which could be used cold, when it was very slow drying, or could be stoved in the ordinary way, but it is not now procurable. Possibly, if you wrote to Messrs. Mander Bros., varnish makers, 2-4, Noel Street, Soho, London, W.1., they could help you.

D. J.—Impossible to say what amount of bicarbonate solution is sufficient for, say, 50 self toning cards, since different brands of paper are liable to vary considerably as regards the amount of

bicarbonate which is required. As bicarbonate is so cheap and is used in such weak solution you should use plenty of it. There can be no possible reason that we can see for trying to economise in it. There is no need to wash in changes of water before inserting in the fixing bath.

W. L. G.—We do not think you can buy zinc with the required grained surface. At any rate, we have never heard of its being supplied. But any photo-engraver should be able to etch for you zinc in almost any required pattern, either by photographing a textured surface, or by laying down one or other of the numerous patterns of shading medium. We think if you applied to the photo-engraving firm which ordinarily makes your blocks they could give you what you require.

C. J.—Aluminium is not a suitable metal for developing dishes owing to its being strongly affected by alkalies. Since amidol is made up without an alkali it is the developer which is most suitable for aluminium, but even an amidol developer is slightly alkaline owing to the sulphite having a certain alkaline reaction. So far as we know there is no chemical action between aluminium and amidol, nevertheless it would not surprise us if the amidol developer caused staining and slight roughening of any aluminium dish in which it was kept for any length of time.

S. L.—(1) There is no objection to cream colour on the studio walls unless the sun is upon the glass during the day, when it would cause the negatives to be rather flat. If your ruby lamp is safe there is no reason why your dark-room walls should not be white. We have daily experience in a dark room which has very light grey walls, and although the most rapid plates are used there is no trace of fog. The dishes are not covered, nor is any unusual precaution taken. (2) We think it is quite necessary to use the makers' formulæ for papers giving special tones. We have not obtained as satisfactory results with "Kodura" and "Vitegas" when using amidol as with the special metol-hydroquinone recommended. If you want to keep to one developer metol-hydroquinone is the most convenient.

W. W.—(1) We have found that the minimum power necessary is 6,000 c.p., and this is best applied by having six 1,000 c.p. lamps. (2) The General Electric Co., Magnet House, Kingsway, London, W.C.2, who will give you an estimate. (3) Nothing except the G.E.C. booklet. (4) It is largely a matter of expediency. In an ordinary glass roof studio many prefer to put the lamps on the solid side of the roof, so as not to interfere with ordinary lighting, while others place them on the glass side to use in conjunction with poor daylight. The lamps should be placed about 8 ft. from the sitter's end of studio, and should go up to 8 ft. from the floor for full lengths, and come down to about 5 ft. for sitting figures and babies. They should be arranged in a slight curve so that two lamps serve as a side light.

C. J.—(1) Diamidophenol, which is the same thing as amidol, but different from paramidophenol, is usually sold in the form of hydrochloride, which is a combination of the "base" with hydrochloric acid. We expect that both of your samples are this hydrochloride. Very frequently, in fact as a rule, the hydrochloride is sold simply under the name of diamidophenol. (2) We are not able to identify the gas burner, which is evidently of French make, but we are pretty sure that it is not made for ordinary house gas, but for acetylene. It seems to be an arrangement for burning acetylene under a small mantle, although we have never heard of a burner of this type. If it is an acetylene fitment, Mr. R. J. Moss, of 98, Snow Hill, Birmingham, would no doubt be able to fit the necessary accessories. "Déposé" on the burner means registered. We have no means, however, of ascertaining the name of the registered firm from the number.

C. R. W.—So far as our experience goes photographers do nothing towards warming the water supply used for washing prints in cold weather. Certainly, as you say, the efficiency of the wash water is less when cold, though considering the large excess in which the water is used we do not think that that makes very much difference as regards removal of hypo, providing the prints or negatives have been thoroughly fixed. It makes a great deal of difference, however, in the comfort of handling plates or prints. It would be an easy matter to arrange for a small coil water heater to be connected with the water supply. For raising the temperature from about 40 to 60 the consumption of gas would be relatively small, and a sufficient flow of water could be obtained. Messrs. Fletcher Russell, of Warrington, make a number of patterns of water-heater suitable for this purpose, one of which, we see, is regularly listed by Messrs. Sinclair, of 54 Haymarket, S.W.1, as a valuable dark-room fitment, which is what it is

P. T.—Acetylene is very little used in portrait work, and we have not been able to find any installation in use. We are of opinion that it is quite suitable for the purpose, but are unable to say what candle-power would be necessary. Much would depend upon the length of exposure you can afford to give, but we should imagine that 500 c.p. would be the minimum. Replying to your inquiries:—(1) 7 litre burner, 14 c.p., consumption ¼ cubic foot of gas per hour. 14 litre burner, 30 c.p., consumption ½ cubic foot of gas per hour. 21 litre burner, 50 c.p., consumption ¾ cubic foot of gas per hour. (2) Yes, at equal visual candle-power. (3) A very rapid ortho plate, such a Marion's Iso Record. (4) If the burners are well distributed we do not think that a diffuser would be necessary. (5) It is impossible to compare acetylene with other lights, except on a basis of cost per exposure, and we have no data available to do this. So far as we can ascertain there is no lamp or arrangement of burners suitable for photography now on the market. We would, however, recommend you to apply to Messrs. Thorn and Hoddle, 151, Victoria Street, Westminster, London, S.W.1, or Mr. David Allan, 107, Mansfield Street, Kingsland, London, E.2, who have made such apparatus. (7) Milton is an efficient hypo eliminator; only a very weak solution is necessary, about one part in 100 parts of water.

W. S.—(1) Providing that the facts can be established beyond question respecting your having taken the photographs at your own cost and with your employer's permission, we think you are the owner of the copyright. If the case came into a County Court the judgment would rest purely on the evidence. Prima facie the copyright in photographs taken by you as an employee is the property of your employer, and therefore it would be necessary to be able to show quite clearly that you were taking them under special conditions. If the evidence was conflicting on the point, we think it is more likely than not that judgment would be given for the employer. (2) Your second query perplexes us by apparently contrary claims which it seems to imply. You have made an enlarged negative from one of those referred to under (1) and have sold it to your employer. Very good, that is certainly evidence that your employer admits your ownership of the copyright. This is the strongest piece of evidence you could bring in claiming copyright of the exposures mentioned under (1). Now you also say that you wish to claim the enlarged negative by paying for the cost of enlarging. We are quite at a loss to understand what you mean. We should have thought that as you had sold the enlarged negative to your employer you had also undertaken the costs of making it. If those costs were undertaken by your employer, we think you have no case whatever, either for copyright in the original subjects or for any right to purchase the enlarged negative. But the facts are not as clearly put as they might be, and perhaps we are misunderstanding the circumstances.

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 3215. Vol. LXVIII. FRIDAY, DECEMBER 16, 1921. Price Fourpence.

Contents.

SUMMARY.

Mr. H. O. Thompson describes the making and electrical wiring of a vertical enlarger which he has made at small cost and which has rendered valuable service. (P. 746.)

The conditions which apply to the choice and care of apparatus in a tropical climate are usefully instanced by some notes on his experience by a photographer in Java, who adds a description of his method of developing films under tropical conditions of temperature. (P. 744.)

In a contributed article Mr. D. Charles suggests a short educative series of tests in the making of development prints. (P. 743.)

Mr. A. Lockett contributes a note on simplified formulæ for the calculation of telephoto separation. (P. 747.)

The requirements as regards lighting and exposure which are determined by the colour of the subject are of importance in portraiture, and equally in the photography of commercial articles. (P. 742.)

Messrs. Loyd A. Jones and C. W. Gibbs, of the Eastman Research Laboratory, have described the method used in measuring the absorption of light by tinted or toned cinematograph picture films, and have brought together a large number of their results, showing the considerable increase of projection light which is required for normal brilliancy of such coloured pictures on the screen. (P. 747.)

At the Royal Photographic Society, on Tuesday evening last, Dr. G. I. Higson drew attention to the advantage of potass. persulphate over ammonium persulphate as a reducer. A paper by Dr. S. E. Sheppard dealt with the effect of iodides and cyanides on emulsions. Mr. F. C. Toy contributed a note on the adjustment of Goldberg wedges; and Mr. F. F. Renwick gave a demonstration of the properties of a new filter for ultra-violet light more effective than aesculine and without the drawbacks of impermanence and German origin of the latter. (P. 753.)

In a letter to the "Times" of Tuesday last Professor R. Melville Jones describes the experimental programme which is now being carried out in the Faculty of Aeronautics of Cambridge University for establishing the conditions under which sufficiently accurate maps may be prepared by aerial photography. (P. 750.)

Further information respecting the 1922 Congress of the Professional Photographers' Association is forthcoming to the extent that the venue will be Princes Gallery, Piccadilly, and that an exhibition of portraiture from foreign studios is to be arranged, in addition to that by professional photographers in this country. (P. 741.)

A Congress of northern photographers was mentioned at the annual dinner of the Edinburgh Society of Professional Photographers. (P. 754.)

A system of producing speaking cinema films and the design of a roll-film holder are among the patents of the week. (P. 751.)

Students of the perennial subject of depth of focus may be interested in being reminded of the various meanings attached to the term "hyper-focal distance" in writings on depth. (P. 742.)

The practical drawbacks, which are attached to the use of the incandescent acetylene light are briefly described in a paragraph on page 741.

EX CATHEDRA.

Acetylene Light. Last week we replied to a correspondent who sent to us what appeared to be a burner for acetylene to be used under an incandescent mantle and stated that we were unaware of burners of this type being in use. Messrs. R. J. Moss & Sons, the well-known acetylene firm of Snow Hill, Birmingham, very kindly send us some particulars bearing upon this matter. They tell us that mantles for acetylene incandescent burners are made by Messrs. George Bray, of Leeds, and by many Continental firms, and they confirm us in our opinion that very few such burners are in use. While, theoretically, a burner of this type gives more light for a given consumption of acetylene than the self-luminous flame, the colour of the light is not so good. But the chief objection to this form of acetylene light is the very great difficulty of keeping the minute air passages free and thus of burning the gas with a proper adjustment of air. Even with coal gas, which is burnt at the rate of from 3 to 5 feet per hour in an incandescent burner, care has to be exercised in providing proper adjustment of the air; the difficulty is greatly increased in the case of an acetylene atmospheric burner consuming from one-quarter to one cubic foot per hour. For these reasons incandescent acetylene as a light-source for projection and enlarging lanterns has not proved a satisfactory plan in practice. Although when in new and perfect working order a burner consuming one foot per hour will be nearly equal to two self-luminous burners consuming two feet per hour, very slight variations in pressure of the gas or in its degree of purification and drying so greatly upset the action of the burner as to render it useless.

The 1922 Congress. The letter from the secretary of the Professional Photographers' Association, which appeared on page 739 of our issue of last week, adds little to the information which had so far been made public respecting the arrangements for the Congress of next year, which will celebrate the coming of age of the Association. It does, however, tell us that the Congress is to be held at the Princes Galleries, Piccadilly, London, W., and that it is hoped to supplement the exhibition of portraiture by photographers in this country by exhibits from leading studios in other countries. We are cordially in agreement with the view that next year's Congress should assume a special character worthy of the completion of the twenty-one years of life of the P.P.A. We hope to be reassured by the further announcements which are to be made that this aim will be better realised in Piccadilly in September than at the Horticultural Hall in May. In our opinion the crux of the choice between these two times and places resides, not in physical facilities, but in entirely human considerations, chief among which is the question whether professional photographers in sufficient number will attend the Congress at the end

of the summer. We are inclined to think that the attractions in the displays of apparatus, etc., at the Fair rank at any rate equally with those of the Congress meetings in the estimation of the rank and file of members of the P.P.A.; and if that is so, it is at least questionable whether a September Congress has the same chances of special success which one in May would have in Vincent Square. From what we can hear exhibitors at the Fair (who, we are informed, have without exception rebooked their space) are satisfied that they will get the attendance of professional photographers, and we have no doubt that Mr. Arthur Brookes will provide other special features making the Fair specially attractive to portrait photographers.

* * *

Hyperfocal Distance. Photographic literature suffers from many examples of confusion of terms, but it is perhaps more unfortunate than in most other instances that the somewhat involved subject of depth of focus should include in its vocabulary a term, namely hyperfocal distance, which is used by various writers in three different senses. Most usually, perhaps, it is employed to denote the nearest distance of an object to the camera which is rendered without perceptible unsharpness when the lens is focussed on infinity. By others it is used to denote the distance of an object from the camera on which one should focus in order to obtain infinity without perceptible unsharpness. There would not be much objection to these two senses of the term, since the two distances are very nearly the same, differing from each other in fact only by one focal length of the lens, which, in most cases, can be entirely neglected. It is not the same, however, with the meaning which is attached to the hyperfocal distance by French writers on optics, notably Moessard. In French papers on the subject the term hyperfocal distance is employed to mean the distance of the nearest object which is obtained without perceptible unsharpness (according to the particular standard adopted for the disc of confusion), when objects at the extreme distance corresponding with infinity are rendered in like manner. A very simple geometrical construction shows that hyperfocal distance, according to this last definition, is one-half that according to either of the two former. These differences are, perhaps, the cause of some of the misunderstandings which habitually occur in discussions of depth of focus.

* * *

Self-Toning Papers. The paper read by Mr. P. R. Salmon at the South Suburban Photographic Society, which appeared in last week's "Journal," usefully drew attention to the very considerable variety which exists at the present time among commercial self-toning papers, not only as regards facilitating the production of certain colours in the prints, but also as regards contrast. From being in its early days the favourite paper of the amateur, a popularity which it has still retained, self-toning paper has come to be the stand-by of many professional portraitists, more especially those who work practically single-handed. It is, perhaps, the opinion among those who have not interested themselves particularly in self-toning papers that the latter are all much of a muchness in requiring a somewhat vigorous negative, that is to say, a negative of a kind which is not the best for gaslight printing or for the making of enlargements. It is therefore worth while to direct attention to the detailed notes contained in Mr. Salmon's paper, from which will be seen the opportunity which exists for choosing among self-toning papers those which are specially suitable to soft or to vigorous negatives in reference to the degree of contrast which is desired in the prints. Doubt upon this point has very likely deterred individual portrait photographers from making greater use of the self-toning type of paper. So far as surface, texture and colour of the paper base are concerned it is surely not necessary to point out that makers have provided between them all the variety which is ordinarily called for.

THE INFLUENCE OF THE SUBJECT UPON LIGHTING AND EXPOSURE.

The variations in treatment which are rendered necessary by differences in the colour and surface of various subjects, including the human sitter, do not always receive at the hands of the photographer the attention which is due to them, and therefore the results, although perhaps passable, are by no means as good as they might be.

Technical or commercial photographers do not usually err in this respect, but the average studio worker is rather apt to go on with his subjects as if they were as much alike as is a row of pins, and to attribute his poor negatives to some wickedness inherent in them rather than to his own ignorance.

Let us take a familiar example, a wedding cake. How often do we find full detail in the high-lights as well as the shadows, and the texture of the surface correctly rendered throughout? Very rarely indeed. To go to the other end of the scale, the same may be said of a dark bronze figure or a carved ebony panel. Assuming that in each case the plate is capable of taking care of the colour rendering, it has been found by actual experiment that the bronze statue will require thirty times as much exposure as the wedding cake, plate speed and lens aperture and lighting being, of course, identical.

In practice it is, however, undesirable to use the same kind of lighting for such widely dissimilar subjects, for the glaring white cake requires a very subdued illumination, while the bronze will stand any amount of light, even the direct rays of the sun not being too much for some antique specimens. In either case it is important that the exposure should be sufficient to give full detail with a reasonably short time of development.

The colour of the subject, apart from its whiteness or blackness, as exemplified in these two instances, has a very important bearing upon exposure, not only when the colour is pronounced, but when it exists in such delicate shades as are hardly perceptible to the eye. If when copying a series of engravings mostly upon white paper one printed upon a slightly yellowish india tint is encountered, it will be found necessary to give three or four times the exposure necessary for the others, if it is to have the same degree of contrast.

In the case of subjects which show extremes of light and shade, such as machinery with polished steel for lights and dark green or brown for shadows, sufficient exposure must be given to secure detail in the latter. If the plate be backed and a diluted but unrestrained developer be used, it will be found that a fairly accurate representation of the subject as it appears to the eye will be obtained. It must never be forgotten that density accrues in the high-lights much quicker than detail appears in the shadows, and that the loss of detail in the former more than compensates for any gain in the latter. In passing, it may be noted that very rapid plates are not as a rule suitable for subjects with strong contrasts, their scale of tones being shorter than that of slower ones.

We have so far dealt only with inanimate models, as our points can best be illustrated by such, but the same idea holds good in ordinary studio portraiture. Although

such extremes of white and black rarely occur, there is enough variety in the complexions and dresses of sitters to call for some modification of lighting and exposure. Taking the question of complexion first, it is obvious that a pale-faced woman with undistinguished features and, if we may say so, a generally washed-out appearance demands a lighting which, while subdued in the high-lights, provides sufficiently strong shadows to give a proper idea of relief, while a rubicund soldier whose palest flesh tint is a deep yellow will stand a strong illumination and free use of the reflector. Although, perhaps, foreign to our subject, it is not out of place to advocate the use of colour-sensitive plates for all portrait work, there being no circumstances in which they are inferior to the ordinary variety, while in many cases they give perceptibly better results without a light-filter. With difficult sitters, such as those having blue eyes and golden hair, the improvement resultant upon the use of an orthochromatic plate with a pale yellow filter is so marked, that once seen it will not be forgotten.

Although it is just now a fashion to ignore clothing and draperies in portraiture and to present the face in a sombre surrounding, it is sometimes required to give full details of these, and it may again be fashionable to do so. Sometimes a difficult problem such as a pale lady in a black velvet dress, will present itself. Here a full exposure is necessary if the result is not to be hard. If only sufficient exposure be given for the proper rendering of the face, there is a great temptation to over-develop in trying to get some detail into the velvet, but with a fuller exposure this detail can be attained before the shadows in the face are lost. The face may be a little lacking in contrast, but at least it will have the texture of flesh and not that of a plaster image. With such a subject a small head screen may be used with advantage, placing it so that the light is softened upon the face only and allowed to play in full strength upon the dark clothing.

The old slogan "Get it in the negative" is the soundest piece of advice which can be given. Matt-varnishing, dodging in printing and such devices falsify the scale of tones in the original subject and are apparent to the artistic eye. Correct exposure, careful lighting and judicious development, joined, of course, to artistic posing are the main factors in successful portraiture. It may be necessary to define judicious development, and in the fewest words this may be done by saying "Avoid forcing." No negative was ever improved by trying to get out reluctant detail, and thousands have been ruined by it.

FOR AN ODD HALF-HOUR IN THE PRINTING-ROOM

This is going to be a different sort of article to any I have ever read or written, so it may be new, both in *modo* and in *re*, to others also. The novelty will consist in my asking those who feel inclined to perform certain simple and possibly apparently uninteresting acts, and even to spend a small amount of money in doing so, without my stating the benefit or results that I suggest will ensue. The reason for adopting what may seem at first sight to be an unreasonable attitude is that the benefits cannot fully be obtained by merely reading about them.

First of all I will give a list of the articles required for these experiments. They comprise principally merely part of the ordinary equipment of the printing-room. A big, deep dish of acid-hypo and a whole-plate dish with about a pint of developer; a lamp that really is safe for bromide paper, and the printing-box or machine that is in regular use will obviously be required for a little while, and, in addition to these, I recommend very strongly the acquisition of one of those small plates of graduated densities sold as plate testers or as actinometers for carbon-printing; one with not less than twenty gradations should be chosen. It is possible for the expert photographer to make one for himself, but it is much cheaper in the end to buy one. In addition to this graduated plate, I will ask the experimenter to make a larger and simpler one of four gradations only with overlapping sheets of translucent paper. The bands of gradation might be an inch wide each, and the whole thing may conveniently be pasted by its edges on to the lid or bottom of an empty plate-box which has a fairly large aperture cut in both.

The materials for the tests will comprise a few pieces of printing-paper such as are in regular use, either bromide, gaslight, or one of the crosses between these which are finding great favour nowadays. It will be all the better if several kinds are available, and if a couple of pieces of a slow paper as large as the glass top of the printing-box (or at least the size of the largest negative printed on it) can be spared it will add greatly to the value of the tests. If bromide-paper only is used the effect of the slow paper can perhaps be got by temporarily changing the lamp used for printing with a carbon-filament of low candle-power.

Having arranged these few matters the first thing I will ask the reader to do is to develop a few tiny strips of paper previously exposed on the printing box so as to find the exposure that will produce, on full normal development, a fairly strong grey, but not a black. Having determined this, it is possible to expose one of the large size sheets of the slow paper, and it is very likely that only one will be required. After exposing this sheet, it is to be developed in a bath rather weaker than normal, say half-strength, and while in the bath it is necessary to keep the sheet moving continuously. As soon as the sheet has developed to a fairly strong tint it is washed free of developer under a fairly strong jet of water from the tap, and on immersing it in the hypo it is kept moving from the moment it touches the fixing-bath for, say, fifteen seconds or so. After a further short fixing the sheet may be turned up and examined.

Even from this very simple effort something should be learned. If the tint is beautifully even all over one can be sure, at any rate, that certain troubles must not be attributed to either the paper or the printing-box, but if the contrary is the case it should not be difficult to decide whether one will at last make an effort to give the inside of the printing-box a new coat of white paint and fit it with a sheet of ground-glass an inch or so below the negative, or whether a change of paper is desirable. If any doubt exists as to the cause of any phenomenon which may present itself a second sheet treated exactly like the first will decide the point. If the peculiarities in the two results are identical, obviously they are due to some feature of the apparatus. If not, they must be due to faulty paper.

The next experiment I suggest is to take the plate-box which was cut out and fitted with layers of tissue paper, and lay it upon the printing-box—tissue side downwards. If a piece of printing-paper is then laid upon the box and exposed, it should show a range of tints on development from light to dark, but more or less diffused by reason of the distance between the sensitive surface and the tissue papers. After having exposed and developed one or two pieces to get the hang of the idea, I will ask that a few pieces be treated as follows:—One sheet, on being taken out of the developer, is just dipped in water, dropped into the hypo, and left there. The

second is to be rinsed under the tap in passing from developer to fixing-bath, and the third well washed by a stronger flow of water directed along its surface for more efficient removal of the developer. The two latter are to be well moved on immersion in the hypo. Anything that may be learned from this test will be much more marked in the case of the slow papers, and the same applies to the following one. For this, either the tint negative of tissue paper may be used, as in the previous experiment, or a negative in which there is some area of delicate thin gradation, such as a male sitter in dark clothing, or a negative which has been vignetted in the camera.

The experiment consists in giving two sheets identical exposures but developing them separately, one being kept moving continuously hroughout development and the other being allowed to lie still in the developer till dark enough. Comparison of the two usually will arouse surprise, and it may be remembered in this connection that when more than three or four prints are developed simultaneously in a dish together they are still for a great proportion of the time period of development. It may be added that prints that are fully or slightly over-exposed (as I believe the great majority of bromide prints are) will show a greater difference under this test than correctly exposed prints which are allowed to develop right out.

The last experiment of all is to expose a few bits of paper under the plate of numbered densities, and to develop them right out. Naturally some papers and some exposures will reach a higher number than others, but usually the tints at the lower and thinner end of the plate will produce a certain number of black areas showing no difference. The gradation of any particular paper will start, of course, from the lowest tint that shows a difference in depth from the one before it, and the number of tints from that to the highest which can be just seen against the white paper is a measure of the gradation. A more rapid paper, therefore, which a similar exposure gives a higher number, will not necessarily have a longer gradation, but if it has the fact is easily recognised. Having done this, it is not a difficult matter to compare the highest and lowest densities of the current negatives with the numbered densities of the test plate and so determine whether or not they show a greater difference than those extremes which it has just been found the paper used will register. On the other hand, it may be found that the negatives exhibit a still shorter range of tints. In either case it follows that the negatives are not calculated to make the best possible prints on that particular paper, and either they should be developed differently, or another brand of paper should be selected. Persons are not unknown who are very keen on paper prices, and who persistently ascribe lack of quality in prints to obstinate carelessness on the part of the printer. An occasional half-hour spent in such practical little experiments as those I have described will do more to settle disputes between operator and printer than hours of argument. It is also a good plan to make such tests before sending complaints to a paper manufacturer. When the reader has carried out the simple operations outlined above once or twice he will appreciate that the results will be far more convincing in the case of a dispute than any number of faulty prints. If they are too much trouble for him to perform then I can only retort that to describe why they will be so convincing is too much trouble for me.

D. CHARLES.

PHOTOGRAPHIC EXPERIENCES IN JAVA.

THE information contained in this article is prepared from an unsolicited communication sent to Messrs. James A. Sinclair and Co., Ltd., Haymarket, London, by a customer of theirs, Captain C. S. Blunt, of Batavia, Java, who is an enthusiastic and serious amateur photographer, and writes of his experience in the use of apparatus and the practice of photography in the hot and moist climate of Java. We owe to the courtesy of Messrs. Sinclair the opportunity of putting Captain Blunt's information before our readers.

The Dutch Island of Java, like other places in the East, presents many attractive subjects for the traveller with a camera. With a population, including the island of Madura, of 35,000,000, chiefly native, there are numerous subjects representing native customs and industry, relics of the old religions of the East, all side by side with the modern prosperity which has followed in the wake of the Dutch colonists. Although Java obtains the strong light of the Tropics, at the higher mountain levels the light is often bad, owing to the mist in which hill tops and mountains are generally enveloped. For this reason the user of a camera on a tripod is very frequently better equipped than the less serious worker with a hand camera.

Captain Blunt states that the islands form a fine market for cameras, but one which, unfortunately, is left almost completely in the hands of the Germans. The latter are leaving nothing undone to regain and extend their trade. If a German camera goes wrong, the agent is on the spot to remedy matters or, if need be, to supply a new one. Captain Blunt's report is that British firms are complaining of no business, whilst the German firms are growing fat on their profits. Nevertheless, the preference for British goods exists, but is stultified by the want of accommodation on the part of London firms in comparison with the thoroughness with which the German studies the market. Such is the opinion formed by Captain Blunt from his observations.

Choice of Apparatus.

In choosing a camera for use in a climate such as Java—and the conditions there may be said to prevail more or less throughout the East—the first piece of advice is that, for good results, it should be one with which focussing can be done; that is to say, should be usable on a tripod, when so required. From the point of view of the photographer who takes his hobby seriously and wishes to obtain really good results, the best camera is a quarter-plate "Una," or something like it; that is to say, one which can be used efficiently on a stand and also in the hand. It is also recommended that the outfit should include an extra small camera, such as an N. and G. vest-pocket for roll film.

If a reflex camera is to be chosen, the extremely short exposures given or claimed by makers of most reflexes can be put aside as useless. The exposures that are needed are half-seconds, not of the order of thousandths of a second. Captain Blunt works usually at one-eighth, one-sixteenth, or one-twenty-fourth of a second, very seldom, if ever, at one-fiftieth or one-hundredth, and is of the opinion that the only reflex meeting all the requirements in a country like Java is the Sinclair "N.S.," having a between-lens instead of a focal-plane shutter. A reflex camera should be fitted with an $f/4.5$ lens for facility of focussing under the bad conditions of light which often prevail.

As regards the lens and shutter for the ordinary type of camera, the best selection is a first-rate objective of $f/6.3$ or $f/6.8$ aperture, such as Ross or Cooke. The shutter is preferably of the between-lens type giving accurate slow speeds from 1 second to one-hundredth. Owing to the bad light which is often available, it is more than ordinarily necessary to have a shutter, the speed of which can be depended on, in order that exposure worked out by a meter or otherwise can be accurately given.

In giving the above advice Captain Blunt is taking the

oint of view of the quite serious photographer. Those who ust have a more portable equipment which they can sling er their shoulder or put in their pocket cannot do better an a quarter-plate camera of the Kodak type, but it should e one fitted with a plate adapter in order that focussing ay be done in the case of near subjects, figure studies, etc.

Care of Apparatus.

There is a great deal of exaggeration about the damage hich a camera quickly sustains in a moist, warm climate ke that of Java, which normally is both hot and damp and, uring the rainy season, awful. As a matter of fact, the isks are not great if a little trouble be taken and common ense used. On the other hand, the dampness of the atmosphere causes bellows and other leather parts to be easily ffected, with formation of a kind of green mould upon them a time. Lenses are attacked in a similar manner.

For keeping the camera in good condition, it should be a ule to take it out of its case every morning and give it a ood rubbing down. It should then be placed on a table or hair, where it will get the warmth of the sun, but not in irect sunlight. The aim is to keep it in a dry state. For his purpose it should be put away, not closed, but with every art opened up, in some roomy cupboard where as much fresh ir as possible can get to it. It should be frequently dusted ith a flat soft brush, which should be carried in the case nd frequently used. It is specially necessary to observe aution in carrying the camera about in the sun after a eavy downpour of rain, when the atmosphere is left in a ondition of extreme damp; the camera in these circumtances should be protected as far as possible from the rays f the sun. As a general rule, when on foot in the hot eather, some kind of cloth should be carried over the leather ase in order to protect it from the sun's heat. On no account hould a camera be left to itself for even one or two weeks. If it be constantly kept exposed to fresh air and kept free from dust and dirt, it will not suffer from the trying conditions of the climate.

Lenses require exactly the same kind of care. On no account should they be kept in a room with the lens caps on. The glasses should have as much fresh air as possible. Lenses will occasionally show stains on their surface due to the glass having been touched with the finger. Inasmuch as the hands are in a continual state of perspiration, a certain greasy deposit sticks to the glass. It can easily be removed with a little petrol. A focal-plane shutter, likewise, needs to be "exercised" regularly every day, whether the camera is to be used or not. The blind should be wound and released a few times so as to expose it to the air and to dislodge dust which in time, in conjunction with the damp atmosphere, may give rise to trouble.

Sensitive Materials.

Captain Blunt is emphatic in his experience that plates give the best results. Next to them he places roll film as regards quality of the result and reliability. Film packs have the drawback that in the damp climate the films will stick together, so that when you pull out, say, No. 3, Nos. 4, 5, and 6 may also come out altogether. He would not use film pack larger than quarter-plate, but even with the much smaller 60 × 45 mm. size has had a good deal of trouble due to sticking.

Development.

Loose chemicals sold in Java are unreliable for photography. For security it should be a rule to use well-known preparations such as Burrough Wellcome's "Tabloids" or other bottled branded goods of repute, and in any case to exercise great care in purchasing from local suppliers. The damp climate appears to attack hypo in some way, for if stored in a paper wrapping it will melt, bursting the bag, and possibly doing a great deal of damage to surrounding goods. Hypo should always be stored and carried in sealed tins.

Excellent results are obtained by tank development if done with proper care. On no account must the developer be used unless with a thermometer to test the temperature. In many cases ice must be used for tank development. The best method is to wrap up a lump of ice in a cloth and beat it into practically a pulp. A bucket of water has now several large lumps of ice put into it, so as to keep the temperature of the water under or about 50 deg. The ice pulp is then put into the tank with the developer, and when the thermometer registers 50 deg. or a little under, the film is put in and then the whole tank is put into the bucket of cold water and allowed to remain there during the whole time of development, say, 20 minutes. During this time care must be taken that the temperature of the water in the bucket does not rise above 50 deg. This method will give good results, because it ensures that the developer is working at 50 deg. The great tendency is for the temperature to rise much more quickly in the tank than might be supposed. It is important to see that the rubber band on the lid of the tank fits properly. Sometimes these rubber bands are too big, so that the tank cannot be closed.

In washing, very great care is required, because water which may be running quite cool from a tap for the first few minutes will suddenly be delivered at a temperature of 90 deg. or more. Alum should be used freely before washing.

Lastly, a hint may be given to travellers taking their film exposures to be developed. There are many firms in Java who develop films, and not only will they develop them badly, but in some cases ruin them also. As a rule, it is best to pick out a good Chinaman, who is usually more careful. And a rule should be made to hand in the film pack in the tin case in which it has been supplied. Assistants in these developing firms are often shockingly careless in the way they squeeze or twist a pack in their hands, so that delivery in the original tin is a certain amount of protection against them.

Scottish Photographic Circle Exhibition.—Membership of the Scottish Photographic Circle is open only to those who can demonstrate by their work their fitness to belong to it. The members are all, therefore, pictorial enthusiasts of considerable ability, and the Exhibition now open until to-morrow, December 17, in the rooms of the South Glasgow Camera Club, 43, Bankhall Street, contains much that is interesting. The entries (limited to three per worker) numbered 129, and from these Mr. Archibald Cochrane has selected the 50 prints which form the present exhibition. This rather drastic treatment has resulted in the exhibits being of a uniformly high standard, considerably in advance of the Circle's previous efforts. Only a small proportion of the exhibits are portraits. W. Crooke shows two of his large scale works treated in his usual masterly fashion. R. Creerar and Wm. Findlay appear to work along similar lines, and both show dainty examples of softly-lit pictures of young womanhood. Among the landscapes J. M. Whitehead's three pictures are worthy of particular study. His "Craigmillar" is a very dramatic impression; "A Dream of the Raplock" is perhaps more likely to give general pleasure, while his "Joyous Summer" is joyous indeed. Dan. Dunlop shows "The Cloud" with fine, open-air feeling; "The Flowing Tide" and "Palace Courtyard, Stirling," from which some undesired buildings have been cleverly removed. In "Sand Castles" W. S. Denver seems to have discovered a new foreground, the shadows of a group of adult spectators being used with very pleasing effect. John Baird sticks to his beloved Scottish mountain and flood; his three examples give evidence of the poetic feeling with which he regards nature. "The Goods Entrance" (A. T. Edgely) and "The Arch" (C. E. Jenkins) show that even in smoky Glasgow fine effects are obtainable by those who appreciate the beauty of light. We find bromoil at its best in "The Isle of Ely" (Hector Murchison) and "Loading Sand" (D. L. Taylor). These workers seem to have avoided the loss of quality observable in so many examples of this process.

A HOME-MADE VERTICAL ENLARGER.

The enlarger which I am about to describe owes its origin to the purchase, some years before the war, of a set of square-form 12 × 10 bellows, with a plain front board attached, which was picked up at an auction sale for 5s. A joiner was called in, and the main body of the enlarger, as shown in the photograph ((fig. 1), was constructed and the bellows affixed thereto, the front board being supported upon a pair of wooden arms which, in turn were fixed to a cross piece made to slide between guides fixed upon two of the uprights.

The opening in the top frame of the main portion of the enlarger is 14½ × 11½ inches, so that a 15 × 12 negative can be placed in position between a pair of guide bars, or a nest of carriers (15 × 12 to 12 × 10, 12 × 10 to 10 × 8, 10 × 8 to whole-plate, whole-plate to half-plate, and half-plate to quarter-plate) can be slid in. The wooden frame which is fixed below this opening, and to the lower edge of which the top of the bellows are fixed, is made 15 × 12 inside, with the idea that although the bellows themselves are only for 12 × 10, it would be possible to work from a 15 × 12 negative. It may be said, however, that in practice it is not found that a 15 × 12 negative receives even illumination right up to the edges. Still, it is not often that one wishes to work from a 15 × 12, and no trouble is now found in working from any size of negative from 12 × 10 downwards.

Fig. 1.

Around three sides of the opening on the upper platform is fixed a wood frame about 3 inches in height, to embrace the light-box; and the remaining side, where the negative carriers slide in, is closed in by a sliding panel of wood, which is dropped into position after the carriers are slid in, thus cutting off all outlet of light from within the box.

The original light-box was made of three-ply wood, and was in the first place equipped with a small mercury-vapour lamp, known as the "Bastian." This had an M-shaped tube and a self-tilting rheostat, but did not give even illumination, except with the addition of so much ground glass or opal interposed as to hopelessly increase the necessary exposures, so it was discarded, and a half-watt lamp substituted. This worked all right for small negatives, but was no good for anything over half-plate, and, as we often have to enlarge from whole-plate or larger negatives, the light-box, as shown in the photograph, was designed, and constructed by a local tinsmith. It is fitted with five half-watt lamps—one at each corner and one in the centre, and these are wired up in such a manner (see fig. 2) that it is possible to use the central one only, the four corner lamps only, or all five together. The box is enamelled black on the outside, but the sheet tin of which it is constructed is left bright within which, of course, assists in obtaining even illumination.

The front board carrying the bellows was originally made to work "grip-tight" in its guide bars, but this was only a temporary and never satisfactory arrangement; and after endeavouring for some time to obtain a suitable focussing screw in steel or brass, it was finally decided to have one made of wood, and this has given perfect satisfaction. The bromide paper for enlarging is laid upon a loose drawing board, usually covered by a sheet of good glass, free from flaws and specks. This drawing board is supported upon another board made the full width of the space between the uprights and resting upon cross-bars fixed at convenient heights upon the uprights. An index pointer is fixed upon the sliding board

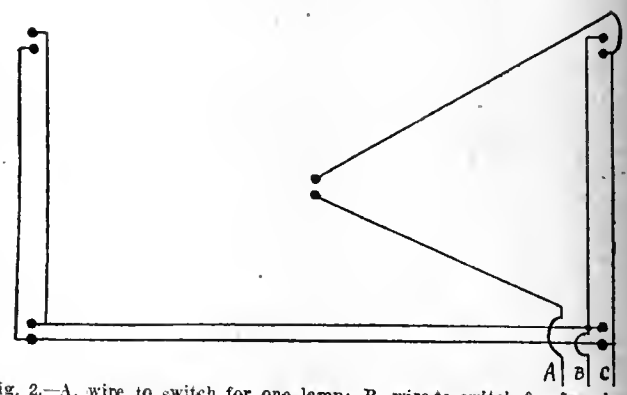

Fig. 2.—A, wire to switch for one lamp; B, wire to switch for four lamps; C, return wire.

which bears the bellows front and lens, and this travels up and down upon a scale fixed on one of the uprights, which shows the degree of enlargement given at any distance with any of three different lenses available, 6, 7, and 8½ inches focal length respectively. It is thus possible to focus rapidly to any desired degree of enlargement by first of all setting the lens board to the scale as required, getting a rough focus by moving a sheet of white cardboard up and down, placing the drawing board in an approximately correct position by supporting it upon a few old discarded pulp boards (at one time used for glazing), and finally getting an exact focus by a slight movement of the screw.

The wider dimension between the uprights of the main frame is 25″, but enlargements can be made to a still greater length than this by placing the negative cross-wise on the upper platform and using a larger board for the bromide paper, also placed cross-wise below. To guard against accidental fogging of the bromide paper, the enlarger is closed in, when in use, by a curtain around three sides of the frame; and it should be mentioned that the top of the light-box, which bears the lamp-holders, is made to lift completely off for convenience in replacing lamps.

The light-box is pierced with a series of ventilating holes on the rear side, well up towards the top, these being trapped for escape of light by a curved plate of tin fixed all along on the outside.

The total cost of the whole affair, which in its present state is giving every satisfaction, has amounted to about £7 10s.—this includes the bellows, joiner's account for wood-work, drawing board for bromide paper, wooden focussing screw, sheet tin light-box, nest of carriers, lamp-holders, switches, wire and lamps. The wiring was done by the writer. A sheet of good ground glass is laid upon the nest of carriers, above the negative, and this is found to give quite satisfactory diffusion of illumination.

H. O. Thompson.

Half-Watt Installations.—In sending us a circular describing their "Dominion" installations for studio half-watt lighting, Messrs. Sichel & Samuelson, 52, Bunhill Row, London, E.C.1, remind us that they were the first to embody the half-watt lamps in a commercial form. They have still in use the original installation and lamps, for demonstration purposes, which they will be pleased to show to any professional photographer who may be interested.

USEFUL FORMULÆ FOR TELEPHOTO SEPARATION.

GENERALLY speaking, writers on telephotography tend to make their formulæ unduly hard of comprehension to the non-mathematical reader. The separation, for instance, required between the positive and the negative lens for a given magnification, is commonly expressed in a roundabout and unnecessarily obscure way, as the sum of the "telescopic condition" and the "optical interval" or "delta" (Δ).

The telescopic condition is the difference between the focal length of the positive lens and that of the negative lens, or f_1-f_2; while the optical interval is the amount by which the separation exceeds the telescopic condition, and may be anything between the latter and the focal length of the negative lens. This, however, merely tells us the limits of the separation, namely, that it cannot be as long as f_1, nor as short as f_1-f_2.

Some may assert that the separation is of comparatively little practical interest, since most adjustable telephoto lenses have a fixed negative element, and obtain variations in magnification (M) by racking out the positive; so that all the worker really has to do is to measure the extension (E) from the negative lens, which equals $f_2 \times (M-1)$. Nevertheless, it quite often happens that the photographer has to employ an extemporised telephoto attachment, fitted inside the camera at the back of the positive lens. In such a case, it is sometimes extremely useful to know the separation, or the degree of alteration necessary.

Disinterred from its undeserved burial beneath the "delta" pyramid, the formula for telephoto separation may be exhibited in the following intelligible and straightforward garb.

Let f_1 = the focus of the positive lens, f_2 = the focus of the negative lens, and, M = the magnification wanted. Then

$f_1-f_2+\frac{f_2}{M}$ = the nodal separation from positive to negative lens.

Thus, suppose the positive lens is of 7 ins. focus, and the negative lens of 3 ins. focus, what separation will be required for four magnifications?

Here, $f_1 = 7$, $f_2 = 3$ and $M = 4$. Therefore,

$$(7-3)+\frac{3}{4} = 4\tfrac{3}{4} \text{ ins. separation.}$$

Magnification, of course, is the quotient obtained on dividing the positive focus into that of the telephoto combination. In the foregoing instance, since the original focus is 7 ins., and the magnification 4, the focus of the resulting combination will be 28 ins.

An alternative formula, giving the separation necessary to obtain a telephoto combination (F) of a desired focal length, is:

$$f_1-f_2+\frac{f_1}{F}\times f_2$$

Thus, suppose the positive lens is of 9 ins. focus and the negative of 4 ins. focus, what separation is required to make a combined focal length of 16 ins?

The calculation here will be:—

$$9-4+\frac{9\times 4}{16} = 5+\frac{36}{16} = 5+2\tfrac{1}{4} = 7\tfrac{1}{4} \text{ ins. separation.}$$

Where a scale of magnifications is marked, as on the ordinary type of adjustable telephoto mount, the photographer often wishes to obtain some other magnification not there included. By using the following formula, this is quite an easy matter, provided the focus of the negative lens is known.

Let M^1 = an existing marked magnification, M^2 = the new magnification desired, and f_2 = the focal length of the negative lens. Then, $f_2 \times \frac{M_1-M_2}{M_1\times M_2}$ = the difference of separation required.

Suppose, for instance, a magnification of 5 is wanted, and the nearest mark on the mount is 3, the focus of the negative lens being $4\frac{1}{2}$ ins. Then,

$$4\tfrac{1}{2}\times\frac{5-3}{5\times 3} = \frac{9}{2}\times\frac{2}{15} = \frac{18}{30} = \frac{3}{5} \text{ in.,}$$

the necessary extra separation, which is readily measured from the existing mark for 3 magnifications.

Even when the focus of the negative lens is not known, it is a simple matter to ascertain it from the distance between any two magnification marks on the telephoto mount. It is merely necessary to multiply together the two magnifications indicated, and divide the product by their difference, multiplying the quotient by the distance (D) between the two marks. Expressed as a formula, this is

$$\frac{M_1\times M_2}{M_1-M_2}\times D.$$

For example, suppose the distance between the marks 8 and 4 on a telephoto mount is $\frac{3}{4}$ in. Then

$$\frac{8\times 4}{8-4}\times\frac{3}{4} = \frac{32}{4}\times\frac{3}{4} = \frac{96}{16} = 6 \text{ ins.,}$$

the focus of the negative lens.

With a telephoto combination having a fixed positive and a movable negative lens, it is not a difficult matter, by means of the formulæ already given, and a few trials, to graduate the sliding tube inside the camera for various magnifications. Since it will, however, be awkward to measure the extension from the negative lens in the usual manner, one may proceed instead by adding together the separation and extension ($s+E$), and measuring from the node of emission of the positive lens, or from the lens-board after making the necessary allowance. Expressed as a formula, let f_1 = positive focus, f_2 = negative focus, and M = required magnification. Then,

(Separation + (Extension)

$$(f_1-f_2)+\frac{f_2}{M}+\left(f^2\times(M-1)\right) =$$

the total distance from positive lens to plate.

A. LOCKETT.

THE ABSORPTION OF LIGHT BY TONED AND TINTED MOTION PICTURE FILM.

A communication from the Research Laboratory of the Eastman Kodak Company.

THE past few years have seen a remarkable increase in the use of toned and tinted motion picture film, and a large proportion of the films made are coloured by some process of toning or tinting. It is quite evident that since the production of colour involves the absorption of certain components of the white light ordinarily used for projection purposes, the screen brightness will in general be less when coloured film is used. While the lower screen brightness may be desirable in the production of certain effects, it may be very objectionable in many cases and demand an increase in the current used in the projection lamp in order to produce a picture of satisfactory brightness. A knowledge of the absorption characteristics of the film coloured by three various toning and tinting processes is of considerable practical importance, and it seemed desirable to make precise quantitative measurements of the amount of light absorbed by films coloured in various ways. This communication is a report of the work done on the subject, and consists of a description of the apparatus and method for the measurement of these values, with considerable data relating to the absorption of light

by samples prepared according to certain definite methods used in the toning and tinting of positive motion picture film.

The photographic deposit of which a picture is built up consists of minute particles of metallic silver embedded in a matrix of transparent gelatine. These deposits are of a diffusing nature, that is, the light transmitted by them is to a great extent deviated from its original direction of propagation and emerges from the film as scattered light. In specifying the transmission or density of such a deposit it is, therefore, necessary to define carefully the conditions under which the measurement of these characteristics are made.

In the case of non-scattering media, the value of transmission is given by the ratio of the transmitted to the incident light intensity. Thus, if

I_0 = intensity of incident light
I_1 = intensity of the transmitted light
T = transmission

$$T = \frac{I_1}{I_0}$$

It has been found convenient in many cases to express the light-stopping characteristics of a material in slightly different terms, this being especially true in the case of photographic deposits. For this purpose another term, namely, "density," is used, and if this be designated by the symbol D its value is defined by the equation

$$D = \log \frac{1}{T}$$

It has been shown experimentally in the case of photographic deposits consisting of particles of metallic silver embedded in gelatine that density is directly proportional to the mass of silver. Density values are additive quantities, that is, if two layers of known densities be superposed their combined density will be equal to the sum of the individual densities.

While values of transmission and density may be thus simply defined in the case of non-diffusing or non-scattering media, this is not true in the case of materials that scatter the light transmitted by them. The light transmitted by a diffusing media may be said to consist of two components:

(a) The "specular" component, which is not deviated from its original direction of propagation by passing through the material.

(b) The "scatter" component which consists of light that has been deviated from its original direction of propagation by the material.

Since a photographic deposit is of a diffusing character, it is usual in speaking of the density or transmission of such deposits to qualify the terms by the adjectives "specular" or "diffuse," the former being applied to the value obtained by using the intensity of the "specular" component of the transmitted light, while the latter term applies to the value obtained by considering both the "specular" and "diffuse" components as transmitted light. In practice, this latter value is usually obtained by illuminating the sample by completely diffused light, such as may be obtained by placing the sample in contact with a piece of diffusing material, such as pot opal glass. The value for specular transmission is measured in practice by placing the sample in a beam of parallel or collimated light in such a way that the transmitted intensity is that of the undeviated rays. It is evident in the case of a cinematograph picture being projected in the usual way that the scattered component of transmitted light is not useful as image-forming light, and that only the specular or image-forming portion of the transmitted light is of interest. From a consideration of the optical characteristics of a motion picture projecting machine it is evident that the density or transmission values of interest are thus almost identical with the "specular" values as defined above. The illumination on the film being projected, however, is not completely parallel, and hence the effective value of transmission may be somewhat different than the true "specular" density. It seems advisable, therefore, in this particular case to measure what may be termed the "projection" density or transmission which may be defined as follows:—

If in a given projection assembly the screen brightness be measured with no film in position, and this value be designated by B_0, and the screen brightness again measured with the photographic deposit under consideration in position and designated B_1, then the "projection" transmission T_p will be given by the relation

$$T_p = \frac{B_1}{B_0}$$

All of the transmission and density values given in this paper and applying to the various toned and tinted samples are computed in this way, and are, from the standpoint of projection, the effective transmission and density values. Since many of the samples are highly coloured, the problem of determining the transmission is further complicated by the existence of colour differences in the photometric field, and in order to reduce the photometric errors to a minimum a flicker method was adopted. By this method the photometric field is alternately illuminated by the two lights which are to be compared, and a means is provided whereby the frequency of alternation can be varied. In case the two lights being compared differ both in colour and in intensity, a flicker due both to inequality of colour and intensity will be present when the frequency of alternation is low. As this frequency is increased, however, a point is soon reached where the flicker due to colour difference disappears owing to a blending of the two colours, while the brightness flicker persists. If, now, the frequency of alternation be maintained at a value just sufficient to eliminate colour flicker, the residual flicker due to brightness—difference may be eliminated by bringing the intensity of the two beams to equality. Since the field viewed is alternately illuminated by the two lights being compared, and the frequency of alternation is sufficient to produce a blending of colour, this field appears to be uniform in colour, and the criterion of photometric equality is the condition of no flicker, no flicker occurring when the intensity of the two beams is equal. In this way the necessity of judging the relative brightness of two fields differing widely in colour may be avoided. The frequency at which the colour flicker is eliminated depends both upon the magnitude of the hue and saturation differences, and in practice if maximum precision is to be obtained, the rate of alternation should be maintained at the critical frequency for the colour difference under consideration. It is the general opinion among photometricians that the flicker photometer provides the most reliable means of comparing the intensity of two lights differing widely in colour.

In fig. 1 is given a diagram showing the essential parts of the instrument constructed for this work. At D is mounted a Whitman disc which is driven by the motor M. Such a disc consists essentially of a circular plate from which alternate 90 deg. sectors are cut away. The surface of this disc is covered with a matt white

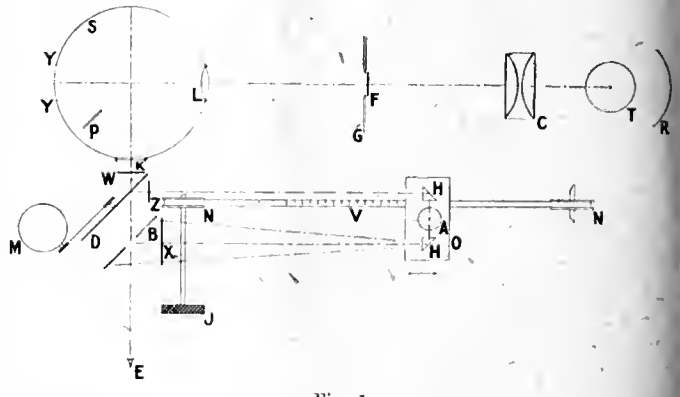

Fig. 1.

paper and is illuminated by the lamp A, which is mounted on the carriage O. This carriage is moved back and forth by means of the steel tape V operating over the pullies NN and actuated by the hand-wheel J. The two total-reflecting prisms HH are also mounted on the carriage C, as shown, so that the Whitman disc D and the screen B are each illuminated to exactly the same extent, regardless of the position of the carriage. Holders are provided so that neutral tint filters may be inserted at positions W. Z, and X, as may be necessary.

The parts thus far described may be regarded as composing the flicker photometer proper, while the parts indicated by the other elements of the diagram represent the special attachment for measuring the transmission of the film. Since it seemed desirable to measure the effect of various toning and tinting processes when applied to the finished positive film, it was necessary to adopt some method of integrating the light transmitted by the treated pictures. Such pictures consist of areas of widely varying density, and in order to determine the mean or integrated value of transmission a small integrating sphere was used. This is represented by the circle S, and consists of a copper sphere 12 inches in diameter, in one side of which is mounted the lens L, and at a point 90 deg. from this the opal glass window K. The interior surface of this sphere is covered with a dead matt white enamel. A metal plate G serves as a support for the film being measured, and in this plate a rectangular aperture of exactly the same dimensions as that in standard motion picture machine is cut.

The film to be measured is placed in position as indicated at F. A 250-watt stereopticon lamp T was used as a source for the illumination of the sample, a reflector R being used to increase the illumination on the aperture plate. The condenser C served to give to the illuminating beam the same convergence as is found in standard projecting machines. The lens L is of such focal length that a sharply-defined image of the film F is formed on the interior wall of the sphere at YY, the magnification being two diameters. A small opaque disc P is placed in position, as shown, and serves to shield the opal glass window K from the direct illumination from the picture area YY. The photomteric field is observed from the point E as indicated, and consists of a circular area, the outer portion of which is formed by the screen, B, while the inner portion, termed the "flicker field," is illuminated alternately by light reflected from the Whitman disc D, and by that transmitted by the opal glass window, K. A photometric setting is made by adjusting the position of the lamp A to such a point that flicker is eliminated from the inner portion of the field, this being the condition under which the brightness of the disc surface is equal to that of the opal glass. In this particular instrument a brightness balance between the outer and inner portion of the field also exists at the no-flicker setting. It is thought that the use of a surrounding field of the same brightness tends to increase the sensitivity of the flicker method since the observer at all times has in the field of vision a non-flickering area which tends to increase his sensitivity to flicker in the inner part of the field. This point has not as yet been definitely verified, but it has been found that readings can be repeated with great precision with this instrument. The comparison lamp A and the illuminating lamp T are run under constant conditions by means of suitable rheostats and indicating instruments. In practice it was found most convenient to calibrate the instrument in terms of the density of the film placed at F. In order to increase the scale of the instrument the multiplying filters must be used at positions W and Z. These also are carefully calibrated in terms of density. From the calibration curve plotted with density values as ordinates and scale readings as abscissæ, the density of any film placed at F can be read directly, and in case transmission values are desired they can be read directly from suitable conversion tables.

Photographs of the complete instrument as assembled are shown in figs. 2 and 3.

The methods of colouring positive film may for the purpose of this discussion be divided into three classes, namely :-

a. Dye tinting.
b. Dye toning.
c. Chemical toning.

In dye tinting the colour is obtained by immersing the finished positive in a solution of dye, which colours the gelatine, thus giving a uniform colour to all parts of the picture. A complete discussion

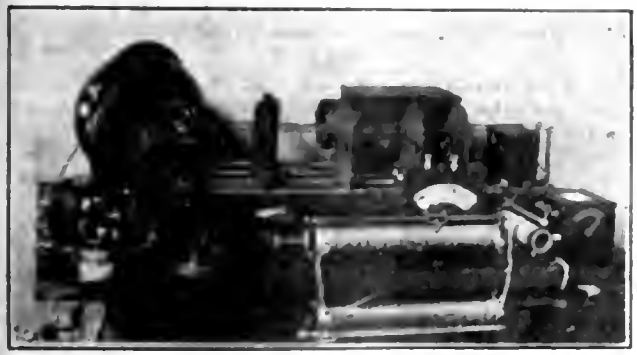

Fig. 2.

of the various processes of dye toning and chemical toning will be found in a booklet entitled "The Tinting and Toning of Eastman Positive Motion Picture Film," published by the Eastman Kodak Company. An article dealing with the subject was published by Mr. J. I. Crabtree in the "Motion Picture News," p. 3255, December, 1918. The results obtained with samples treated by these various methods will, for the sake of convenience, be treated separately.

Transmission of Dye-Tinted Samples

Three types of samples were prepared for each of the various tints examined. The first sample consisted simply of a piece of unexposed, fixed-out positive film, which was subjected to the action of the dye bath for a time sufficient to give the desired colour. Since it is possible that the presence of the silver image may have some influence on the behaviour of the tinting process, the effect produced when the process is applied to a picture consisting of such lights as may be somewhat different from that indicated by the measurement of the fixed-out sample. A typical negative of what was judged to be average quality (from the standpoint of contrast and relative proportion of high-light and shadow region) was chosen and a considerable length of positive printed from a single negative and developed in the usual way giving a normal positive consisting of a large number of identical pictures. In order to illustrate the general nature of the subject chosen, this positive is reproduced

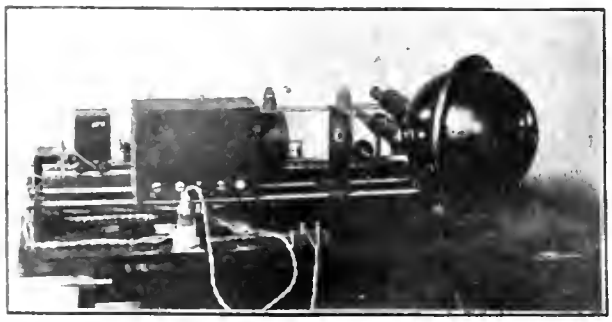

Fig. 3.

as Picture No. 41, in fig. 8 of this communication. Short lengths of this positive were cut and dyed along with the unexposed fixed-out samples, the two receiving identical treatment in the tinting bath.

In order to study still further the effect of photographic density on the result, a sensitometric strip consisting of areas of increasing density was also prepared. These strips were made on ordinary cine positive film and each area of uniform density was of the same size as a standard cinematograph picture and therefore filled completely the aperture in the film holder of the photometer previously described. The minimum density was practically equivalent to the fog density of the material, while the maximum density was approximately 2.8, thus including the entire density range ordinarily used in the production of positives. One of these sensitometric strips was treated along with the two samples previously described, the dye treatment for the three samples being identical. All tests were run in triplicate, so that the values reported are in all cases the mean of three independent detensinations. The various formulæ used for the tinting of the samples examined are given at the end of this communication.

In Table I are given the numerical results obtained with the various samples of tinted film. Under the section marked "Plain Film" are those applying to the unexposed, fixed-out samples, the values in Column D being those of "Density," in Column T those of transmission, and in Column T_r the relative transmission values referred to the transmission of the untinted samples as 100 per cent. Under the section marked "Picture" are the corresponding values relating to the pictures tinted according to the various processes. The A and B variations are obtained by changing somewhat the time of dyeing so as to obtain small variations in the resultant tint, the "A" tint in each case being the lighter, that is, having the higher transmission.

TABLE No. I. TRANSMISSION OF TINTED FILM.

Sample.	Name.	Plain film.			Picture.		
		D.	T.	T_r.	D.	T.	T_r.
0	Untinted	0.055	88	100	0.84	14.5	100
2	Cine red (A)	0.41	39	44	1.18	6.6	45
1	Cine red (B)	0.43	37	42	1.20	6.3	43
3	Cine scarlet (A)	0.36	44	50	1.13	7.4	51
4	Cine scarlet (B)	0.66	22	25	1.43	3.7	25
7	Cine orange (A)	0.20	63	72	0.99	10.0	69
8	Cine orange (B)	0.25	56	64	1.01	9.7	66
5	Cine yellow (A)	0.16	68	77	0.92	11.9	82
6	Cine yellow (B)	0.15	71	80	0.95	11.2	77
29	Cine green, No. 1 (A) ..	0.18	66	75	0.98	10.5	72
28	Cine green, No. 1 (B) ..	0.45	36	41	1.19	6.4	44
31	Cine green, No. 2 (A) ..	0.25	56	64	1.05	9.0	62
30	Cine green, No. 2 (B) ..	0.61	24	27	1.34	4.6	32
26	Cine blue (A)	0.65	22	25	1.44	3.6	25
27	Cine blue (B)	0.81	16	18	1.54	2.9	20
33	Cine violet (A)	0.62	24	27	1.33	4.7	32
32	Cine violet (B)	0.63	23	26	1.43	3.7	26

Measurements on the sensitometric strips show that in general the absorption of the dye is practically independent of the density, although in the case of cine yellow and cine orange there is indication that the high-light region absorbs slightly more dye than the shadow regions; that is, regions of high density. This tends to produce a slight decrease in the contrast, and hence produces a slight flattening of the picture. The effect, however, is not large and does not manifest itself in the case of all tints. The results of the measurements of the sensitometric strips treated with the cine orange are shown graphically in fig. 4, the density values of various

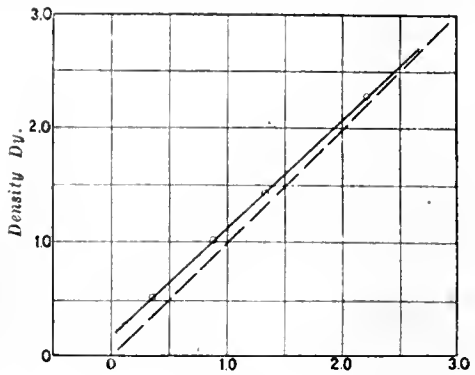

Fig. 4.

areas of the tinted sensitometric strip being plotted against the density values of the corresponding areas of the untinted strips. The points indicated by the small circles represent the results of the measurements plotted in this way. A line at 45 deg. to the X axis and passing through zero represents the line of no density change owing to the tinting. It will be noted that the curve obtained is not precisely parallel to this 45 deg. line, thus indicating that the areas of low density have suffered a greater proportional density increase than those of higher density.

PROGRESS IN AERO-PHOTOGRAPHIC MAPPING.

THE following letter by Professor R Melvill Jones, professor of aeronauties, Cambridge University, which appears in the "Times" of Tuesday last, December 13, provides a short account of the experimental work which is being carried out at Cambridge on aero-photographic methods of map-making.

I notice that in your issue of December 3 you published a leading article on the problem of mapping from the air. It may interest you to know that experimental work on this subject has been in progress at Cambridge University for the last eighteen months. The Royal Air Force have placed at our disposal, for this and other work, a small experimental flight of aeroplanes working at an aerodrome in the neighbourhood of Cambridge. The work is being carried on under my direction, with the close co-operation of the Department of Geography here and with the personal assistance and advice of Captain H. H. Thomas, who is a member of the University and an ex-Air Force officer intimately connected with aerial surveying in Palestine during the latter part of the war. We are also in close touch with the War Office Air Survey Committee and with the Photographic Department of the Air Ministry. The bulk of the work is being carried out by two research assistants, financed by the Department of Scientific and Industrial Researeh.

If aerial photographs are required to provide anything more than a somewhat inaccurate picture of the ground, it is necessary to know with considerable accuracy the angular position of the camera when the photographs are taken, and experience has indicated the order of accuracy that will probably be required before aerial mapping may be expected to compete successfully with detailed ground surveying. Unfortunately, experience has also shown that this order of accuracy is not generally obtainable when the aeroplanes are flown by pilots who are not specially selected or trained for the work.

It is possible, even when large unknown tilts occur, to calculate these tilts accurately by a method known as "resection"—that is, to calculate the tilts from the position on the plates of known ground marks that have been accurately surveyed independently. This method of overcoming the difficulty is being developed in England and other countries; but it is our belief that it will involve the fixing of too many points by independent ground surveying, and that it requires too much office work, in connection with the "resection," to be commercially successful, except in special cases.

The alternative line of attack on the problem that we are following up is to improve the flying until a camera fixed in the aeroplane will seldom vary from the correct position by more than a certain permissible angle, and then to use the photograph without "resection." War experience of experimental flying indicated that it should not be impossible to do this, using selected pilots correctly trained, and our experimental work to date has therefore been mainly directed to the training of pilots and to the calculation of the tilts of the aeroplane when flown by them, in order to discover whether the desired accuracy of flying is being realised.

So far as we are aware, the experimental determination of aeroplane tilts had never previously been carried out with the accuracy and on the large scale which is required for this work, but the problem in our case was rendered particularly easy by the existence, between Cambridge and the Wash, of great stretches of level country well supplied with marks, in the form of drainage canals, which can easily be identified on the plates.

We have to date succeeded in showing that we can, in an experimental flight, reduce the errors of tilt to within the required amount, and we are now engaged on the further problem of flying so as to cover the ground without gaps or excessive overlapping between the strips of photographs whilst still maintaining the accuracy realised in the previous experimental flights. Although we have not yet reached any definite conclusion on this second problem, satisfactory progress is being made, and we hope to be in a position to issue a report on this subject early in next year.

With regard to the determination of contours from the air mentioned in your leading article, we do not propose to attack this problem until we have cleared the ground in respect of the fundamental problem of straight level flying; but it is well known that approximate contours can be obtained by estimation, with the aid of a stereoscope in which two successive overlapping photographs are viewed simultaneously. We are not yet in a position to say whether this method can be developed to give great accuracy.

FORTHCOMING EXHIBITIONS.

December 3 to 17.—Scottish Photographic Circle. Hon. Secretary, W. S. Crocket, 10, Parkgrove Terrace, Tollcross, Glasgow.

1922.

January 21 to February 4.—Partick Camera Club. Particulars from the Hon. Secretary, James Whyte, 51a, Peel Street, Partick, Glasgow.

February 11 to 25.—Scottish Photographic Salon. Particulars from the Secretary, James F. Smellie, Braefindon, Allanshaw Street, Hamilton.

February 14 to 17.—Exeter Camera Club. Latest date for entries, January 30. Particulars from C. Beauchamp Hall, Hon. Exhibition Secretary, Exeter Camera Club, "St. Denys," Bellevue Road, Exmouth.

February 18 to March 4.—Edinburgh Photographic Society. Latest dates, entry forms, February 4; exhibits, February 9. Particulars from the Hon. Secretary, G. Massie, 10, Hart Street, Edinburgh.

March 8 to 9.—Birkenhead Photographic Association. Latest date for entries, February 25. Particulars from the Exhibition Secretaries. Messrs. Longstaff and Trace, 33, Hamilton Square, Birkenhead.

BARGAINS IN VEST-POCKET CAMERAS.—Following their recent list of reflex cameras, issued by the Fleet Street Branch, the City Sale & Exchange has just published from 54, Lime Street, London, E.C.3, a closely-printed 12-page list of bargains in secondhand vest-pocket and 3¼ by 2½ cameras for plates or film. The list contains particulars of scores of cameras of all makes, and is obtainable free on application.

Patent News.

Process patents—applications and specifications—are treated in "Photo-Mechanical Notes."

Applications, November 28 to December 3 :—

MOUNTING.—No. 31,899. Mounting photographs W. H. Collins.

DESIGNS ON GLASS.—No. 31,946. Method for producing photographic designs on glass, porcelain, etc. J. Sobawa.

STEREOSCOPY.—No. 32,355. Means for obtaining stereoscopic pictures. E. H. Wright.

CINEMATOGRAPHY.—No. 31,992 Means for obtaining cinematograph pictures. E. H. Wright.

COMPLETE SPECIFICATIONS ACCEPTED.

These specifications are obtainable, price 1/- each, post free, from the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C.

The date in brackets is that of application in this country; or abroad, in the case of patents granted under the International Convention.

SPEAKING CINEMA FILMS.—No. 157,925.—(January 13, 1920.)—The object of the invention is to provide a process for the recording and reproducing of optical images and sound waves simultaneously, of the kind in which the sound waves are transformed into light-fluctuations the photographic record of which is reduced to such a form that it can be acoustically reproduced by a sound box, such as is made use of in ordinary talking machines. The recording operation, which corresponds to the negative process in photography, is carried out by apparatus which is already partly known, and consists in the fact that the sound waves are received on a diaphragm the vibrations of which are made to influence the direction of a beam of light. The latter, which is protected from dispersion by a stationary screen, falls on a uniformly moved photographic layer (a film) and by creating shades of varying

gradation in the latter produces a symbolic representation of the sound waves. The recording of the pictorial effects is effected on the same film, which, however, is, for this purpose, moved intermittently.

The essential feature of the invention is that reliefs corresponding both to the views and to the sound waves are produced side by side directly on a chrome-gelatine positive film by a purely photographic process.

In the drawing, the diaphragm *a*, responsive to the sound waves, is, by means of the rod *b*, connected with the screen *d*, which is free to oscillate about the axis *c*. Axially opposite to the screen *d* is arranged a second, stationary screen *e*, so that the light-rays *f*, issuing from the luminous source *g* and concentrated by the system of lenses *h*, produce shades of intensities varying with the position of the movable screen *d*, on the film which is made to move uniformly in the direction of the arrow. If the apertures in the screens have the shape of narrow rectangular slits, then, after development, the representations of the sound waves obtained, will take the form of lines *l*, ranged parallel to each other and of shades of more or less pronounced intensity. Since, for the subsequent reproduction, the lines need have a breadth of only 1 to 2 mm. the rest of the film may be utilised for the recording of the pictures. This latter operation is accomplished by the objective *i*. The intermittent motion of the film required for this is permitted by a loop *j* in the film, dimensioned to suit the sound recording. When the film is being developed, exceptional care has to be taken that the sound symbols come out in sharp and strong contrast. Should the picture records, for this reason, be developed either too weakly or too intensely, they may, subsequently be corrected in the positive process.

For the reproduction operation or the positive process, a second film is made use of, containing no silver emulsion and the gelatine layer of which is sentitised by immersion in a solution of bichromate of ammonium or potassium. If now the negative film records be transferred to this chrome-gelatine film, by placing the films one above the other, and then illuminating them and subsequently treating them with warm water, relief representations are obtained of such a kind that positions of greater or less elevation on the positive film correspond to more or less intensely blackened positions on the negative. The film, after this treatment is finished, is drawn through a rather strongly concentrated solution of dyeing material (such as aniline dyes, for example) and the operation continued till picture-records, when held up to the light, seem to be sufficiently distinct, after which the film is washed in weakly acidulated water and dried.

By the dyeing solution, not only do the picture records become more visible but the relief ones are also improved by the elevations and depressions being more pronounced, owing to the absorption of the dye-stuff by the gelatine. Films prepared by this process show pictures of a high brilliancy, as the grain (or imperfectly smooth surface), which otherwise makes its appearance as the silver separates out, is here almost entirely absent. To reproduce both picture and sound effects from such a film, the picture-recording part of the latter is projected, but the part containing the sound-records is made to pass under the needle of a resonating-box, and the motions or vibrations of the needle produced by the elevations and depressions, now create the sound waves which have been previously recorded photographically.

In the process just described, and in contradistinction to other processes, the sound waves are not retained in the form of a sound curve, but by means of more or less intense shadings of the photographic layer, in the form of lines, this layer having an upper surface entirely free from grain and which, owing to its relief form, permits of the use of a stone-pointed needle which does not require to be replaced. Further, in the development of the negative film, the picture and sound records are quite independent of each other and the usual thickness of gelatine is also well adapted for both.—Eugen Reisz, 12, Wilhelmstrasse, Zehlendorf Mitte, Berlin

ROLL-FILM HOLDERS.—No. 149,615 (July 26, 1919). The invention relates to roll-film dark slides in which after each exposure the film band is moved by rotating the receiving drum. The actuation of receiving drums in cinematographs and certain textile machines by means of a friction change gear, the ratio of gear of which is automatically changed according to the gradually increasing diameter of the roller of the wound-on part of the film or band, is well known, *e.g.*, by the Patent Specifications 15,083 of 1901 and 13,471 of 1904.

A corresponding device is desirable for photographic cameras with which a great number of exposures are to be made in rapid succession. In spite of the gradually increasing diameter of the receiving drum, there corresponds to a certain definite angle of rotation of the actuating shaft for the changing device in each case a movement of the film-band by a definite length, viz., that of a picture. Since, however, where a rapid change of pictures is concerned, especially with larger sizes of pictures, there arise disturbances by the mass inertia of the supply drum, to the shaft serving for actuating the receiving drum there is coupled the supply-drum, by means of a friction change gear, and, moreover, the adjusting device for changing the ratio of the gear is coupled with the receiving drum in such a manner that by the rotation of the receiving drum the ratio of the speed of the actuating shaft to the speed of the supply drum is gradually diminished.

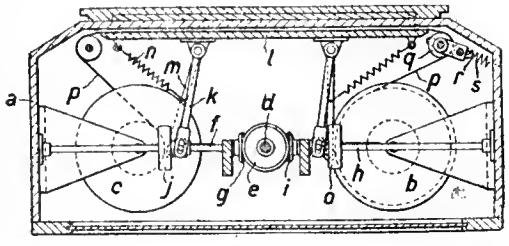
The friction change gear may, for instance, be of a kind in which a plane-face wheel coacts with a spherical-disc wheel, which throughout the following will be referred to as a friction disc, which for the purpose of changing the ratio of the gear is so disposed as to be displaceable along its shaft, and the movement of the member to be displaced for changing the ratio of the gear (hence, in the change gear of the kind referred to as an example, the displacement of the friction disc on its shaft) may, for

instance, be derived from the rotary movement of the respective drum. The adjusting device would then substantially have to consist of a gear by which the rotary movement of the drum is transformed into a rectilinear one, and by which a transformation of the comparatively quick movement of the receiving drum into a slower movement is effected, which may, for instance, be attained by a worm gear.

The adjusting device may be simplified by coupling it with the respective spool by means of a member which is kept in contact with the surface of the part of the film wound on the respective spool, and which is movable parallel to a plane perpendicular to the axis of the respective spool. In this case, by the gradual change of the thickness of the part of the film wound on the respective spool, to the member kept in contact with the surface of the film a movement is imparted which may be made use of for changing the ratio of the speed gear, so that then the arrangement may be made in such a manner that a transformation of the already comparatively low speed of the member kept in contact with the film is no longer required. A special advantage of this kind of coupling as compared with that first mentioned, also consists in that the continual, automatic adjustment of the correct ratio of the gear may not only be obtained by using a film of a definite thickness, but also by using films of any desired thicknesses.

It will not always be possible to make the parts of the film-band wound off the supply drum, when the actuating shaft is rotated by a certain definite angle, exactly equal to the part which is wound up thereby, so that sometimes a warping or an excessive tension of the film may occur. In order to avoid this drawback it is desirable to provide a tension roller over which the part of the film between the supply drum and the receiving drum is passed. By these means an excessive tightening of the film is automatically avoided, also in case the film, after it has been exposed and moved by the length of a picture, is pressed against a glass-plate, or the air-tight frame of a sucking-on device.

In the drawing, in a casing a there are supported a supply drum b and a receiving drum c. A shaft d is provided with a bevel wheel e, which on the one hand engages a bevel wheel g fixed to a shaft f, and on the other hand a bevel wheel i fixed



to the shaft h. The friction change gear for actuating the receiving drum c substantially consists of a friction disc j which may be displaced on the shaft f, and the flange of the receiving drum c, which in the drawing lies in front.

A one-armed lever k, which is fork-shaped at one end and supported on a plate l fixed to the casing a of the dark-slide, in such a manner as to be rotatable about an axis parallel to that of the receiving drum, and which is fixed to a second one-armed lever m, serves for adjusting the friction disc j.

By a spring n, which is fixed on the one hand to the plate l and on the other hand to the lever m, the free end of the lever m which carries a small roller is pressed against the film wound on the receiving drum, so that the position of the lever m, and thereby the position of the friction disc j and the ratio of the change gear becomes the more gradually changed the more of the film is wound on the receiving drum. The arrangement is in that case made in such a manner that, when the receiving drum is empty, the friction disc coacts with a circular ring surface of the drum flange, the middle diameter of which is equal to the diameter of the empty receiving drum, and the friction disc then coacts, when the drum is partly or entirely wound on, the film-band having any desired thickness, with a circular ring surface of the drum flange the middle diameter of which is equal to the outermost diameter of the drum containing the exposed part of the film, so that in each case the film-band is moved by the length of a picture by a rotation of the actuating shaft d through the same angle.

The change gear for actuating the supply drum contains a friction disc o, which is displaceable on the shaft h and coacts with the front flange of the supply drum b. The friction disc o is gradually adjusted on the shaft h according to the thickness of the part of the film wound on the supply drum b, in the same manner as the friction disc j on the shaft f. The film, marked p, is from the supply drum first passed over a roller q, which is so disposed as to be displaceable in slit r in the front and back side-wall of the dark slide, and which is under the action of two tension springs s (of which only one is visible in the drawing), by means of which the film is continually kept tight.—Firm of Carl Zeiss, Carl Zeiss-strasse, Jena.

APPLICATIONS FOR REGISTRATION.

KALO.—No. 418,128. Chemical substances used in photography, photographic plates and photographic films. Ilford Ltd., Britannia Works, Roden Street, Ilford, Essex, manufacturers of photographic plates, paper and films. August 31, 1921.

ARISTAR.—No. 419,456. Camera lenses. Bloom's, Ltd., 7, Ridgmount Street, London, W.C.1, opticians and photographic dealers. October 12, 1921.

New Apparatus.

The Victor Mitre Cutter. Made by Henry Lawson, Pittenweem Fife, Scotland.

THIS appliance is a mitre-cutting board fitted with an extremely solid metal guide for the saw, and providing the means of accurately and quickly cutting mouldings to the required 45 deg. angle. It consists of a heavy base of hard wood occupying a bench space of 12 x 21 in., and surmounted by an equally heavy superstructure of wood on which is pivotted a metal box, or chamber, midway through which is a guide for the saw. This guide-box occupies one or other of two position at an angle of 90 deg. to each other, and is firmly held in each by a heavy flanged nut on the pivot on which the guide-box turns. A pair of screw stops on the supporting framework provides the means of adjusting the angle of the guide-box to a nicety. The moulding is laid on the board below the guide, an extension piece measuring about 3 ft. being clamped on to support it. With this extension piece the overall length of the appliance is about 4 ft. 6 in. There is an adjustable stop, fixed by a flange nut, for keeping the moulding in the exact position for the cut.

In operation the appliance is very simple. A length of moulding is first put on the board so as to make the first mitre cut with the minimum of waste. The saw-guide is then turned over on its pivot into the other position, and the moulding being now pushed against the adjustable stop in the position appropriate to the length of moulding required, a second saw cut is made; and so on for each of the four pieces for the frame.

The positive and accurate guidance given to the saw by the guide-box is such that anyone of very small skill in the handling of tools can cut the mitre joints with all the required accuracy. We have nothing but praise for the thoroughly solid and substantial build of the appliance and its very simple design. Complete with heavy 16-inch saw it is supplied at the price of £4 10s., including boxing. Mr. Lawson supplies also other appliances for frame making, and a circular describing the various patterns of cramping machines which he supplies will also be of interest to those making their own frames large or small.

New Books.

Photograms of the Year, 1921. Edited by F. J. Mortimer, London: Iliffe and Sons, Ltd. 6s. net and 8s. net.

The harvest of the year in pictorial photography is again effectively gathered (with selection) by Mr. Mortimer in the handsome volume which has just appeared. While one finds in it many of the works which attracted chief attention at the exhibitions held during the past twelve months, its pages represent the pictorial work of photographers scattered throughout the world. The excellent reproductions are given an added educational value by Mr. F. C. Tilney's running criticisms and appreciations of them. And Mr. Mortimer, whilst obtaining extremely fine reproductions from his engravers, shows a nice sense of art editing in the arrangement of the sixty odd pages of plates. While we are sometimes left wondering what are the motives which have prompted inclusion of some of the works in the volume, we can enter into the spirit of gentle raillery which has prompted, for example, the opposition on pages xxviii. and xxix. of the study of a pierrot, who is hardly there at all, and that of "Betty in Her Attic," another scheme of emptiness, which perhaps would have been just as good a thing if Betty had left the place to the play of lights and shadows on the bare floor and walls. As at the exhibitions, portraits and figure studies outnumber the landscapes, and it is perhaps a sign of the present running after sensations in figure studies that there are only three or four landscapes which rise above an ordinary average of work, namely, those by Charles Job, L. Misonne and Alex. Keighley; the latter's, a romantic rendering of a little bit of mountainous country.

In the articles which follow Mr. Tilney's notes, we obtain some short accounts of the interest which is being taken in pictorial photography in the Scandinavian and Latin States, America, Canada, Australia, New Zealand, South Africa and Japan. In these countries, as in the United Kingdom, "Photograms of the Year" worthily takes its place again as a recorder and preserver of what has recently been accomplished.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

MONDAY, DECEMBER 19.

Birmingham Photographic Art Club. Midland Federation Slides.
Bowes Park and District P.S. "Colour Photography." Paget Prize Plate Co.
Bradford Phot. Soc. "Elementary Bromide Printing—Contact Method." Bernal Riley.
Dewsbury Phot. Soc. Members' Lantern Evening.
Forest Hill and Sydenham P.S. "What to See in an Old Church." H. Creighton Beckett.
Glasgow and W. of Scot. Amateur P.A. "Cornwall: The Delectable Duchy." Donald V. H. Smith.
Kidderminster and Dist. P.S. "The Making of a Lantern Slide." A. Dordan Pyke.
Leeds Camera Club. "Child Photography." J. Haswell.
Southampton Camera Club. "Old Processes and New Methods." W. F. Slater.
South London Phot. Soc. Jumble Sale.
Wallasey Amateur P.S. Competition: Holiday and Outing Prints.
Walthamstow and Dist. P.S. Affiliation 1920 Competition Prints.

TUESDAY, DECEMBER 20.

Royal Photographic Society. Lantern Meeting, "The Chamounix Valley." C. Ralph C. Petley.
Birmingham Phot. Soc. "Working up the Exhibition Print." E. A. Bierman.
Exeter Camera Club. "Enlarging." F. Walker.

SATURDAY, DECEMBER 24.

Accrington Camera Club. Xmas Eve Social.

ROYAL PHOTOGRAPHIC SOCIETY.

Meeting held Tuesday, December 13. Mr. F. F. Renwick in the chair.

Dr. G. I. Higson, D.Sc., F.I.C., read a paper on "Potassium Persulphate as a Reducer." He first showed the method employed for exhibiting the action of a reducer upon a scale of densities, viz., by plotting the percentage reduction of each density against the original densities. In this way the action of a reducer, which acts proportionately on all densities, is shown by a straight horizontal line: one which acts more or less on, say, low densities is shown by a corresponding inclination of the line, whilst other abnormalities are represented by the curve of the line.

Potass persulphate differed from ammonium persulphate in being much less soluble, and, therefore, more readily purified by recrystallisation. Its action was accelerated by acids and by traces of copper and iron salts; when used as a plain solution in distilled water it exerted considerably greater proportional action on the heavier densities. Dr. Higson described its characteristically erratic behaviour when a certain quantity of chloride was present, and proceeded to discuss his observations in reference to the theory of persulphate reduction.

A paper by Dr. S. E. Sheppard, entitled "The Action of Soluble Iodides and Cyanides on the Photographic Emulsion," was read in abstract by Mr. K. C. D. Hickman, who gave an account of the experimental work, and discreetly permitted himself to transmit the theoretical conclusions in the form of quotations verbatim from the paper. Dr. Sheppard's observations of the fogging effect (on subsequent development) produced by treating plates with iodide solution had been contested by Mr. Renwick, who had shown that the effect of the iodide on Ilford plates was to produce red-sensitiveness. By further experiments Dr. Sheppard had confirmed his original results, obtained on Seed plates, and also the specific red sensitising when Ilford plates were used. The action of iodide, and also of cyanide, thus took specific forms, varying with the nature of the emulsion. With Eastman commercial film, strong red-sensitiveness had been obtained.

Mr. E. C. Toy, M.Sc., then read a note on "An Improvement in the Goldberg Wedge," in which he briefly described the occurrence under certain conditions of curved markings on plates exposed behind a Goldberg gelatine-pigment wedge. He explained how the defect was permanently cured by interposing a thin strip of paper between the wedge and its front cover glass, and also between the wedge and the plate.

Mr. Renwick then gave a demonstration of a new absorption filter for ultra violet light, replacing æsculine. The substance employed was an aceto-amino-quinine, which was one of a series prepared by Miss Hamer, of Cambridge University, which had been examined in the Ilford laboratories. It absorbed ultra-

violet light much more perfectly than æsculine (a German monopoly), was practically non-fluorescent, and also was much less susceptible than æsculine to darken on exposure to light. Mr. Renwick showed the action of the first filter which had been prepared commercially.

Votes of thanks were accorded to authors and readers of papers.

CROYDON CAMERA CLUB.

Messrs. G. A. F. Gildea and W. E. Tapper, in place of Mr. Gooch, at very short notice undertook to demonstrate the merits of "Vitegas," one of the products of Kosmos, Ltd., and judging by the pictures on the walls a very good paper indeed, yielding by development a fine warm-black, a long scale of gradation, and, all important, a luminous image.

The president, Mr. John Keane, in his short introductory address, must have cheered the somewhat youthful visitors by expressing a conviction that in all probability they would leave the premises alive. Mr. Gildea, looking a little preoccupied, then rose, mentioned that Vitegas is neither a gaslight nor a bromide paper, that the image gradually builds up, and exposure should be adjusted to the fixed time of development, which is 1½ minutes. He followed with some general information (all comprised in an excellent booklet issued by the company), and then suggested an immediate adjournment to the dark-room.

Judging from reports furnished by half-asphyxiated members who emerged at intervals, three successful enlargements were made, and sepia toning was demonstrated. Finally, all returned, were regaled with free samples on a generous scale, and the discussion began

Mr. Walker mentioned that only on one glossy developing paper had he secured good sepia tones, and that one was Vitegas. Considering that he consistently experiences disaster at every turn, the fact that the paper is Walker-proof is a testimonial of great value. Mr. Wadham, alluding to a Vitegas bromoil paper, said an absent member had tried it, and the results were bad eggs. "The bromoil paper is not yet on the market, but shortly will be," politely said Mr. Tapper, a nasty tap for Mr. Wadham. Mr. Harpur, afflicted with a severe cold, wheezed his usual anathemas against bromoil, and the president and secretary and other criminals addicted to the vice. "Is it not a fact that you have given it a good trial and dismally failed?" tenderly inquired Mr. Salt, a question which so aggravated Mr. Harpur's indisposition as to render him quite inaudible. Mr. Purkis next obliged with a few remarks on scientific development, and Mr. Moody spoke in high terms of the results he had secured on the paper. It also transpired that Vitegas can be pronounced in more ways than one without any loss of quality. Oxford does it one way and Cambridge another. Billingsgate and other districts would doubtless add to the number. A hearty vote of thanks was accorded for a thoroughly practical demonstration of a product which all considered possesses real merit.

EDINBURGH SOCIETY OF PROFESSIONAL PHOTOGRAPHERS.

The fourth annual dinner of the Society was held on Monday, December 5, 1921. Mr. John Campbell Harper, President of the Society, presided over a company of thirty-four ladies and gentlemen. The guests of the Society were Mr. William Crooke, photographer, Edinburgh; Mr. Morley Fletcher, Director of the College of Art, Edinburgh, and Mrs. Morley Fletcher; and Mr. and Mrs. Robert Scott.

The President, in proposing the health of Mr. William Crooke, the guest of the evening, referred to Mr. Crooke's pre-eminence in artistic camera portraiture, not only in Edinburgh, but the whole world over. He said that Mr. Crooke's position in photography, which had been gained by consistent hard work and study, was unique. The high standard and quality of Mr. Crooke's work merited recognition and great praise wherever it was exhibited. Mr. Crooke had gained many honours in photography at exhibitions both at home and abroad, and his recent success in winning the "Tacoma Cup" over allcomers in Vancouver, had brought distinction, not only to himself, but also to photographers in Edinburgh, and the Society of which he was an honoured member. The President conveyed to Mr. Crooke the cordial congratulations of his professional brethren in Edinburgh, and wished him in their name long life, health, and prosperity.

Mr. Crooke, in reply, gave an interesting retrospect of his early career. He said that it was absolutely essential if a photographer was to be a success that he should have an extensive knowledge of art. He deprecated the word "posing," as he thought it was the duty of the photographer to interest the sitter in a subject which appealed to him, so that a mental picture of the sitter might be obtained. The recent honour which he had gained at Vancouver was unexpected and unsought. He had been asked to send some of his work for exhibition in Vancouver, and in complying with the request he had merely the desire to further the interests of photography in that country. He highly appreciated the honour which the Society had done him in inviting him as a guest, and for all the kind words which the President had said about him.

Mr. Robert Scott proposed the toast of the Edinburgh Society of Professional Photographers, and in doing so congratulated Mr. Harper on his being appointed President for the coming year. He complimented them on what they had achieved in getting classes for lighting and composition started at the College of Art, and a class for optics and chemistry inaugurated under the auspices of the Edinburgh Education Authority. He said that this Society's work had been closely followed by the photographers' societies in England and elsewhere, and had aroused great interest amongst them. He strongly urged the Society to maintain its position as leader and to go forward towards greater achievements. He thought that the time was most opportune for combining forces with the Glasgow and District Society, and the formation of a northern federation to embrace the provincial towns. He thought that the Society should seriously consider holding a Congress here, combined with a photographic exhibition of members' work.

Mr. E. D. Young suitably replied, and said that he associated himself with every word which Mr. Scott had said in regard to forming a northern federation, and he was sure that the Society would undertake the ground-work, which would be a task of some magnitude and importance.

Mr. E. D. Young, in proposing the toast of "The Guests," Mr. and Mrs. Morley Fletcher and Mr. and Mrs. Robert Scott, said how much the Society was indebted to Mr. Morley Fletcher for his indefatigable support and influence in getting the classes for photographers at the College of Art made a reality. Mr. Robert Scott, he stated, was one of themselves, and had gained the esteem and respect of his fellows by his happy nature, his strenuous activity on their behalf, and his sterling loyalty.

Mr. Morley Fletcher, in reply, said that his wife and he felt greatly honoured by being invited as guests of the Society to their annual dinner, and they highly appreciated the members' kindness. He said the directors of the College now looked upon the class in connection with the photographers as a permanent part of the College curriculum. He was sure that under the able tuition of Mr. E. D. Young and Miss Grey, they would be much appreciated by the pupils. Mrs. Morley Fletcher, in returning thanks, gave a delightful and dramatic rendering of two stories from Æsop's fables, which gave much enjoyment.

Mr. Pelham S. Moffat, in a humorous and racy speech, proposed "The Ladies," and Miss Grey, in her usual graceful and accomplished manner, returned thanks.

Mr. Philip, Mr. E. D. Young, Mr. William Crooke, Mr. Yerbury, Mr. Hutcheson, and Mr. Gordon Brown contributed songs during the evening, which were thoroughly enjoyed, and Mr. Lennie's entertainment and Mr. Nelson's recitation also gave great pleasure to the company. Mrs. E. D. Young acted as accompanist, with much acceptance.

Mr. E. D. Young proposed a vote of thanks to the chairman, who, in reply, said that if the Society existed only for the annual dinner, it warranted its existence after the jolly evening they had spent together.

A vote of thanks was also moved to the vocalists and entertainers, members of the Society and guests who had contributed so much to the evening's enjoyment

The company broke up after singing "Auld Lang Syne."

News and Notes.

MR. R. B. FISHENDEN has resigned his position as director of the inting department of the Manchester College of Technology, after teen years' association with that institution, and has accepted position at the London office of Messrs. Stephenson, Blake & ., type founders, 33, Aldersgate Street, E.C.1. On leaving nchester, Mr. Fishenden was presented with a sectional book- e by the part-time evening staff of the College and with a Shef- ld plate tea service by the Printing Crafts' Guild, as tokens of regrets felt in his severance from these associates.

PHOTOGRAPHERS OF PHILADELPHIA newspapers and local motion- ture enterprises have banded together in an association of otherhood to "create a better understanding between the staff otographers of the many publications in Philadelphia using otographs and to incorporate among camera men a higher sense their duty while working on important assignments." The iladelphia News Photographers' Association is declared to be in no sense a labour union." An organisation meeting was held November 23. At that time, Walter Crail, of the "Public dger," was elected president; Charles M. Clark, of the Fox ws, vice-president; and Stanley D. Levegrove, manager of the Ledger" Photo Service, secretary and treasurer. The associa- n has affiliated with similar organisations in Washington, New rk and Boston.

THE POPULARITY OF LANTERN LECTURES.—The Lecture Agency ates that the leader of the Mount Everest climbing party, Mr. orge L. Mallory, is giving an account of their experiences early January on behalf of the committee of the expedition. This, the t of a series, will be at Queen's Hall on January 10, and the ory, illustrated with wonderful mountain photographs, will be of ceptional interest. Commenting on this announcement, the Evening News" "Man About Town" writes:—"Lecturing, ntrary to the generally held opinion, has not suffered from the mpetition of the cinemas. So far from there having been a slump ere has been, since the war, a greater demand than ever for really st-class lecturers, especially in the industrial districts. Draw a ne from Cardiff to Hull on the map and north of it there is ughly a ten times stronger demand for lectures than in the South. hat is apart from London of course. The mining centres are eat patrons of the first-class literary or scientific lecture."

DEVELOPING TANKS

To the Editors.

Gentlemen,—We have been reading your comments in the cur- nt issue of the "British Journal of Photography" on develop- g tanks, and as photographers who have adopted this method tirely with Eastman portrait film we find that your remarks do t apply, at least, to the above mentioned film. During the whole me we have used this system we have never had an unevenly veloped film, neither have we ever found it necessary to rock e tanks or agitate the solution in any way, the films being erely placed in the tanks (in the Eastman hangers) and left for e requisite period, and when taken out, they will *always* be ound to be without blemishes of any kind.

Yours faithfully,

REGINALD W. BROWN & SON.

Boulevard Studio, Weston-super-Mare.
December 12.

Commercial & Legal Intelligence.

NEW COMPANIES.

THOMAS EVANS AND SON (PENDLETON), LTD.—This private company was registered on December 1 with a capital of £1,500 in £1 shares. Objects: To take over the business of photographers, photographic material printers, formerly carried on by T. Evans in Whit Lane, Pendleton. The first directors are:—H. N. Evans (permanent governing director), 7, Whit Lane, Pendleton; J. Jones, Claremont Road, Pendleton. Qualification: 100 shares. Remuneration of H. N. Evans, £350 (with an additional £150 per annum as governing director); of J. Jones, £250 per annum.

BARON PRODUCTS CO., LTD.—This private company was registered with a capital of £5,000 in £1 shares. Objects: To acquire land, buildings, and hereditaments in England for the erection of a factory, etc., for the manufacture of cameras, emulsions, plates, papers and photographic materials etc. The first directors are:—H. R. Smith, 4, Hereford Road, Southsea; G. H. Meades, "Havenholme," Havant, Hants.; P. H. Palmer 1a, Addington Terrace, London Road, Portsmouth (all provision merchants). Qualification: 100 shares. Secretary: G. H. Meades. Registered office: 27, St. Thomas's Street, Portsmouth.

Answers to Correspondents.

In accordance with our present practice a relatively small space is allotted in each issue to replies to correspondents.

We will answer by post if stamped and addressed envelope is enclosed for reply; 5-cent International Coupon, from readers abroad

Queries to be answered in the Friday's "Journal" must reach us not later than Tuesday (posted Monday), and should be addressed to the Editors

J. A. D.—For enlarging dense negatives there is no better light-source than a small enclosed arc lamp. The Westminster Engineering Co., Victoria Road, Willesden Junction, London, N.W.10, make an excellent sound small model.

J. N.—As a general rule the lens should be *slightly* higher than the head of the sitter, and the camera pointed down until the figure is properly centered upon the plate. The camera should be higher for a person with a short nose than for one with a long one. With children sitting on the floor, or on a low stool, the camera must be brought down as far as necessary, sometimes within two feet of the floor.

E. GARDINER.—We have several times comes across old lenses bearing the same monogram as yours. They were sold by various dealers 40 or 50 years ago. The specimens we have seen appeared to be ordinary French portrait lenses. Before the introduction of the *f*/value system, every maker had his own way of marking diaphragms. Some made No. 1 the largest aperture and some made it the smallest. The numbers, therefore, bear no relation whatever to the apertures or the exposures.

E. F.—We should try carefully rubbing over the whole negative with purest essence of turpentine from the chemist, renewing the turpentine frequently on the cotton wool as medium is removed by it from the negative. If turpentine does not remove the medium entirely you might try immersing the negative in ether and gently rubbing it therein with cotton wool. Remember that ether is most highly inflammable, and must on no account be used in a room where there is a naked light.

W. H. D.—The separate A and B solutions of the "B.J." pyro-soda developer will keep in satisfactory condition for at least a year. The one-solution glycin developer keeps for a much longer time. We have used glycin paste, made according to this formula, years after it has been made up. The metol skin ointment has no special virtues for ordinary cuts or sores. There would be no object in using it in preference to a good antiseptic ointment, such as one made with vaseline and boric acid.

D. O. S.—If you can have electric current supplied to the studio at a cost which is not prohibitive, we most strongly advise you to use electric light instead of gas. There is no comparison as regards efficiency and convenience between a half-watt electric installation and a gas mantle one. We do not answer your questions regarding the latter because we are perfectly convinced that you will think our advice good when we suggest that you should give up the idea of gas and consider putting in electric mains, and providing a half-watt installation of, say, 4,000 to 5,000 c.p. distributed among four to five 1,000 c.p. lamps. Your place is particularly unsuitable for gas on account of its lowness, and in summer the heat from the twenty or so incandescent mantles, which are necessary, would be very great, unless you had very special means of ventilation.

E. B.—We can tell you how to clear off slight veil before intensifying, although not in the exact formula that you ask for. At the same time it seems an unsatisfactory state of things to have to do this reduction and then intensifying in order to get decent negatives for platinotype printing. The best means of clearing off slight veil is to make up the Farmer's reducer by adding a few drops of 10 per cent. potass ferricyanide solution to, say, 2 ozs. of 10 per cent. hypo solution You mustn't put the negative into this mixture, but you must apply it with a tuft of cotton wool to the negative. Add only enough ferricyanide to make a pale yellow mixture. If it acts too slowly, add a little more ferricyanide, but you mustn't overdo the action (we mean make it too quick) otherwise you will play havoc with the quality of the negative. By going over the negative from end to end and crosswise with the reducer you should be able to clear away veil from the shadows without perceptibly affecting other parts of the negative.

G. C.—(1) The usual blue toning formula, which is a better one than that which you quote in your question, is the following :—

10 per cent. solution ferric ammonium citrate...	2 ozs.	10 c.c.s.
10 per cent. solution potassium ferricyanide	2 ozs.	10 c.c.s.
10 per cent. solution acetic acid ...	20 ozs.	100 c.c.s.

The well-washed prints are immersed in this bath until the desired tone is given. Then well wash until high-lights are clear. This bath intensifies the image.

(2) The "Lanternscope" was supplied years ago by the firm of Tylar, of Birmingham. The apparatus simply consisted of a large magnifying lens fixed at one end of a box, whilst at the other was a to-and-fro carrier for the slides. Any optician could fix up a similar kind of appliance, for example the Premier Optical Co., 63, Bolton Road, Stratford, London, E.15, could do it for you. The most scientifically adjusted viewing apparatus of this kind is the "Verant" of Zeiss.

G. F.—We presume that you (1) wish to obtain more colour in the pink printing negative, and (2) to find some means of securing a silver image on a non-stretching support so as to enable you to work up prints made from each negative. (1) Instead of under-exposing the pink negative give a full exposure and development, and after development reduce the negative until thin in the middle and lower tones; then intensify with mercuric bromide and blacken with any non-staining developer, or if extreme contrast is required blacken with cyanide of silver. On the positive it is possible to obtain still further contrast by reduction and intensification. When making screen negative use a 100 ratio for the screen distance, and for the shadow stop either v/64 or v/96 to secure extreme contrast. (2) With regard to obtaining a silver image upon a non-stretching support. Use Kodak Transferotype paper and transfer the film containing the silver halide, before exposure or development, to opal glass, as given in the directions. When dry print on this film from negative and develop and fix as for bromide paper. Or coat opal glass with iodised collodion and sensitise in the usual silver solution, expose and develop with half strength iron developer, and before fixing re-develop with metol silver, the following being the formula :—

A.—Water, distilled	20 ozs.
Metol	144 grs.
Citric acid	96 grs.

First flow over the positive with the above A. and well drain, again flow over plus one-third the amount of the following solution B :—

B.—Distilled water	10 ozs.
Citric acid	130 grs.
Silver nitrate	½ oz.

After sufficient density has been obtained, wash and fix in 2 per cent. hypo, or 2½ per cent cyanide of potassium. Varnish negative with 5 per cent. gum dammar varnish, and when thoroughly hard lightly rub over surface with fine cuttlefish powder, so as to secure a tooth to enable the film to take pencil work, etc.

E. E. W.—(1) The book you refer to is "The Air-Brush in Photography," by G. F. Stine, published by the Abel Publishing Co., 421, Caxton Building, Cleveland, Ohio, U.S.A., price 3.5 dollars. (2) As regards persulphate it is not possible to recommend any special formula. The average formula of 10 or 20 grs. of ammonium persulphate in 1 oz. of water usually works quite well, with the addition—as is necessary—of a drop of sulphuric acid to about each 2 ozs. of working solution. The trouble with persulphate is that the commercial samples vary somewhat. We advise you to use that of Lumière. A little while ago MM. Lumière published a paper on avoiding irregularity in the use of the persulphate reducer. It would probably be of assistance to you, and no doubt MM. Lumière would send a copy on application to Lyons. The negative should preferably be dry when put into the reducer, and should be taken out a little before it has been sufficiently reduced and put in 5 per cent. sulphite solution to check the action of the bath sharply. (3) So long as prints are not given too much exposure and therefore are somewhat superficially developed, the developing formula (M.Q. or amidol) does not make much difference in the colour of the toned prints, either hypo-alum or bleach and sulphide. From your specimens it seems that you prefer a somewhat purplish tone, although many people would like the browner tones of the larger portrait specimens. You will get less staining in the whites with hypo-alum than with bleach and sulphide, but we are afraid we cannot see how we can say anything to help you beyond this. (4) As you are tied down to the use of the particular plates and cannot use a screen, the best thing you can do is to develop with a hydroquinone formula made up with caustic soda, similar to that in the 1921 "Almanac." This will give a great deal more contrast than M.Q. If the contrast is not sufficient, you can increase it by developing slightly, or reducing with Farmer's reducer if you develop fully, and then intensifying with Monckhoven's intensifier. Another plan is to re-copy the negative again on your process plate, and from the positive transparency make another negative, again on a process plate. The two extra stages enable you to get a considerable increase of contrast.

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 3216. Vol. LXVIII. FRIDAY, DECEMBER 23, 1921. Price Fourpence.

Contents.

SUMMARY.

With next week's issue (December 30) it is hoped to include, as a Supplement, the index to the "British Journal" for the present year.

In a recent paper on the method of producing warm tones due to colloid silver by means of tin salts, Dr. F. Formstecher points out the special application of the process to self-toning papers. (P. 759.)

In a paper in "American Photography," Mr. Arthur Hammond usefully emphasises the importance of view-point and the unimportance of the focal length of the lens in determining the perspective rendering in photographs. (P. 761.)

In a leading article we give some hints to the beginner in professional portraiture on the equipment of a small studio as regards blinds, wall and floor coverings, furniture and backgrounds. (P. 758.)

The Professional Photographers' Association has appointed nine sub-committees to deal with the arrangements for the Congress to be held in September next. It has also obtained a concession in the supply of electric current at a reduced rate; and at a special general meeting has finally authorised the measures which have recently been in progress for its registration under the Companies' Consolidation Act. (P. 769.)

The awards made by the judges are published in the competition organised by Messrs. Wellington and Ward in which prizes amounting to £1,000 are distributed in part to professional photographers for the most beautiful portraits of women and in part to the sitters. (Pp. 758 and 770.)

A recent judgment in the High Courts exhibits the extraordinary view which can be taken in law of "personal luggage." (P. 757.)

Fish glue, supplemented by aid from the retoucher, will allow of satisfactory job being made of a broken negative. (P. 758.)

Particulars of the design of a portrait lens for which greater depth is claimed, and details of envelopes for daylight changing of dry-plates are contained in recent patent specifications. (P. 767.)

On Wednesday, in last week, the new mills erected by Messrs. Pirie's Photographic Paper Co., Ltd., for the manufacture of photographic raw and baryta-coated paper were formally opened. It was mentioned that during the war, with facilities inferior to those which have now been provided, Messrs. Pirie manufactured 1,000 tons of raw paper base. (P. 765.)

The Scottish National Salon will be held at Hamilton from February 11 to 25 next. The prospectus and entry form are now obtainable. (P. 770.)

The two chief causes of failure in making the iodine-cyanide reduced are the subject of a paragraph on page 757.

Considerable additions have been made to the collection of geological photographs preserved for reference at the Museum of Practical Geology. (P. 770.)

EX CATHEDRA.

Personal Luggage. The view taken by some of the railway companies recently that photographic apparatus carried by a passenger should be subject to a charge because it is not "personal luggage" has come into prominence lately. Some companies are endeavouring to impose this charge, although the Professional Photographers' Association recently ascertained that the rules of the Great Western Railway provide that cameras or photographic apparatus, up to 60 or 80 lbs. may be carried by the passenger without extra charge. A case which bears on the question was heard in the High Court on December 12 in connection with a charge made by the Great Western Railway Company for a violoncello which a professional musician had taken with him on two journeys. Mr. Justice Horridge and Mr. Justice Shearman declined to give a definition of "personal luggage," but fell back on that of Chief Justice Coburn, namely, that it is luggage which "is personal to the passenger and carried for his use or convenience." Accordingly, they held that a violoncello carried by a professional player was not personal luggage, whence it is to be inferred that the same article if carried by an amateur would come in the category of "personal." The solemn processes of law lead to so many comic conclusions that the foregoing will not arouse surprise. At any rate, the judgment may be regarded as a warning that, so far as cameras are concerned, it is not very likely that the Courts would hold a different view as between amateur and professional photographers taking apparatus with them on a railway. The man in the street will very properly ask how it is that such questions as these have not been settled by an officious and heavily remunerated Ministry of Transport in a way which does even justice to members of the community.

* * *

Iodine-Cyanide. Queries which reach us respecting inactivity of this reducing or clearing solution can usually be traced to one or other of two causes. The first concerns the making of the iodine solution. Although iodine flakes dissolve almost at once in a strong solution of potassium iodide, they dissolve with much greater difficulty in a weak solution, and, owing to the dark colour of the solution, undissolved iodine may escape notice. The best way to dissolve the iodine is to mix the flakes with the required quantity of the potassium iodide and then to add only just enough water to dissolve the latter. The iodide then dissolves almost instantaneously and remains in solution when adding the further required amount of water. By working in this way less potassium iodide may be used, a consideration in view of the high cost of this chemical. The second cause is the very variable quality of commercial potassium cyanide. For this reason it is very little use to prescribe a definite proportion of cyanide solution for

admixture with a given quantity of iodine solution. The best plan is to use cyanide guaranteed of 80 or 90 per cent. strength, when the mixture should work with the required activity when made up in the round proportions which are given in the various formulæ. On the other hand, a less pure sample of cyanide will require a larger quantity of the solution in order to produce an active mixture with the iodine.

* * *

Broken Negatives. The disaster of a broken negative is an ever-present contingency which must be met as the printer best can. Several excellent ways have been published, that most frequently recommended being the cementing of the broken pieces with Canada balsam. This is hardly applicable to the ordinary studio in which there is rarely any balsam to hand, nor, what is more important, anyone who can use it, for Canada balsam is very sticky, and especially so where not required. Any good fish glue, such as is sold under various names, Seccotine, Mendine, and others is equally effective, although the refractive index is not the same as that of the balsam, which, by the way, does not render the crack invisible. The broken edges should be very thinly coated with the glue and brought into contact while the negative is lying on a flat, wooden surface covered with thin paper. A few push-pins should be driven in round the edges to prevent movement, and the whole put away in a dry, warm place for a couple of days. When dry, a thin line of opaque should be painted over the join so that there is a white line in the print, this being much easier to work out than the unequal shadow of the crack.

* * *

Lagging Behind. The showcases and windows of portrait photographers are always interesting, whether the contents be good or bad, and we have often felt that a little heart-to-heart talk would be beneficial to many of our friends. When visiting many of the smaller towns we have often been struck by the amount of utterly out-of-date work that is being shown by old-established men. It is not enough now to make a sharp, well-exposed negative and to print it upon glossy P.O.P. if a discriminating public is to be satisfied, nor is the situation improved if bromides of very poor quality are shown in addition. The poorer class may accept these, knowing of nothing better, but those residents who periodically visit the larger towns where the work is often of the highest class, may be excused if they patronise the photographers there instead of their own townsmen. The latter have the matter in their own hands if they will only awake to their opportunities and use to the full the suggestions which displays by the large photographers contain. A day or two spent in studying the styles shown by the masters of the art, followed by a demonstration of bromide and gas-light printing, would be the best investment many of our country friends could make.

* * *

The Wellington Competition. On another page of this issue Messrs. Wellington and Ward announce the names of the prize winners in the unique competition which closed on November 30 last. It will be remembered that Messrs. Wellington offered £1,000 in prizes for the most beautiful portraits of women. Moreover, the arrangements provided for the award of substantial prizes to the sitters in addition to those to the photographers, thus offering a special inducement for people to be photographed by a given date. We learn that the success of the competition has been thoroughly shown by the thousands of photographs which have been entered, each photograph necessarily representing an order from a new sitter, or a further one from a former customer. T judges, namely, the Earl of Carnarvon, Lady Diana D Cooper and Mr. Alfred Ellis, had a difficult task in maki the awards, for the entries represented a very high quali of work. There can be no doubt that the prints su mitted in this competition would form in themselves exhibition of the utmost interest and educative value professional photographers. We are therefore glad hear that Messrs. Wellington and Ward are not resti on the oars of their enterprise, but intend to make f use of the photographs which have been brought t gether. It is hoped that before very long at least a sele tion of the pictures will be available for inspection at t Wellington Gallery, 101, High Holborn, London, W.C. We imagine that visitors to the Photographic Fair ne May will have an opportunity of seeing them.

EQUIPPING A SMALL STUDIO.—I.

It is a matter of some difficulty for the beginner portrait work to obtain the most efficient equipment f his studio at a reasonable cost. If he can afford to gi carte blanche to one of the large dealers he can rely being well served, but he will probably find that t salesman's ideas are rather expansive, and that he provided with a good many items which are not essenti and which he would be glad to exchange for others wh he has gained a little experience.

The young photographer who has served a prop apprenticeship, usually follows in the steps of his mast and procures as nearly as possible duplicates of t apparatus with which he has been accustomed to worl This is not a bad plan if his employer has been an up-t date worker, but this is not always the case, and th beginner will often find that he could have started at le cost and with more convenient tools, by getting outsid advice if he is not confident of his own judgment. If h be an amateur carpenter he can effect a considerabl saving by making many of his own fittings, such article as reflectors, background frames and the like, calling fo very little skill in construction. We would suggest tha the first outlay should be that of fifteen pence for a cop of "The Portrait Studio," in which he will find sketche of some of the most necessary fittings.

Assuming that the studio is entirely bare, the firs step is to provide an efficient system of blinds or curtains In our experience the latter, although only costing fraction of the price of blinds, are more satisfactory, bot for ease in working and effectiveness in controlling th light. The festoon system should be used for the to light and straight curtains in two rows for the side. I the studio has a single slant or high side-light the matte is further simplified, as all the curtains will be upon on plane. Dark blue, dark green or black casement cloth and white nainsook or madapollam are satisfactor materials. Black or other dark-coloured Bolton sheetin is more durable, and is recommended where much sun light falls upon the glass; though more costly at th outset it is much more durable and in the long run i probably cheaper.

If the floor is not in sufficiently good condition to stair and polish, it should be covered with plain linoleum, which may be had in various colours to suit the tint o the walls. A small carpet should be placed at one end, as it is not only useful for full-length figures and posing children, but gives a cosy and finished effect to the studio. It is not advisable to cover all the floor with carpet, a this makes the camera difficult to use and adds considerably to the work of keeping the place clean.

Some means of warming is essential, and for thi

purpose we do not think anything is better than the closed stoves in which anthracite is burned. These can be kept going night and day during the winter; there is no labour of lighting daily and the studio never gets cold. In a studio so warmed snow will only remain on the roof in the most severe weather. If gas be preferred it is a good plan to use it in a radiator which can also be kept going continuously. Open fires, either for coal or gas, are to be avoided, as there is a risk of setting fire to light draperies or of children burning themselves if left unwatched for a moment.

Furniture is the next consideration, and considerable judgment must be exercised in its choice. Modern taste has banished "photographic" furniture from the studio. No longer are to be seen such monstrosities as multiple back chairs and weird settees which were never to be found in any dwelling; their places have been taken by reproductions of good specimens of more or less antique chairs and tables. These may be found at the principle photo-stock houses, or they may be purchased of the ordinary furnishing establishments; the latter, however, are not always willing to sell single chairs, and the photographer should avoid having duplicates of any one pattern. Even the reception-room furniture should be chosen with a view to its use in the studio as needed. We must here repeat a word of advice which we have already given, that is, not to buy any chair, settee, or other seat without having observed the effect of a lady model in it. The arms of many chairs are very unsuitable for posing the figure gracefully, and no matter how fine the design may be otherwise this point must never be overlooked. A set of grouping stools of various heights is a very useful thing, not only for groups, but for providing seats of various heights for bust portraits.

Backgrounds are now much simpler than they were a few years ago, when a considerable number of interiors and exteriors were regarded as necessary. For a small studio four, each measuring eight feet by six, or if there is room eight feet square, will be found sufficient. One black, or nearly so; one white, with a floor extension; a suggestion of foliage and a medium-toned cloud will meet nearly all requirements, although two small graduated or cloud grounds about seven feet by five will often be found a useful addition. All backgrounds should be strained upon frames and fitted with castors so that they can be moved without effort to any part of the studio. Next in importance to the backgrounds come the reflector and the diffusing screen. The former may be home-made and consist of a frame about six feet by three feet fixed upon some easel-like arrangement, so that it can be tilted to any angle. There are some excellent reflectors made in two sections, each of which is pivotted, but these are rather expensive just now. The diffuser or head screen should be purchased, as it is likely to be rather clumsy if home-made. It consists of a circular wire frame covered with cheese cloth, and fitted upon a metal support provided with universal movement. This is a most useful appliance, and should on no account be omitted from the studio fittings. A second diffuser covered with black gauze will often be found useful for subduing the light upon the lower part of a figure, but it is not as essential as the white one. The camera and lenses, together with dark-room and printing apparatus will be dealt with in another article.

COLLOID SILVER TONING WITH TIN SALTS.

[Among the many methods of toning development prints to warm colours, that by means of tin compounds is of special interest, since the coloured images which are obtained contain metallic silver in the colloid form. Attention was first drawn to this method of toning by Neugschwender some ten years ago, and was the subject of detailed investigation by Miss Bertha E. Woolley and Mr. Charles W. Gamble, whose experiments were published in the "B.J." of December 26, 1913, pp. 978-991. In a recent issue of "Photographische Rundschau," Dr. F. Formstecher, in a communication from the Mimosa research laboratory, describes further experiments in this method of toning.—Eds. "B.J."]

The use of tin salts in the toning and intensification of the silver images on prints and negatives was first made by Neugschwender[1] in particular application to bromide prints. The method which he used seems, however, to be still scarcely known. Yet it is, as later experiments have shown, the best form of this process of toning. Two years later Desalme[2] is mentioned as the discoverer of the same process, in which also Namias[3] has made some experiments. At the time of the outbreak of war the method appears to have been forgotten (Dr. Formstecher apparently is ignorant of the paper by Woolley and Gamble.—Eds. "B.J."), and has recently been revived by Pokorny[4], who, however, recommends a very unsuitable form of the method. The process, therefore, appears deserving of further attention on the part of technical photographers.

Apart from its practical usefulness, the toning of prints with tin salts possesses considerable theoretical interest. Unlike all other toning processes, in which the silver of the image is either replaced by some other substance or converted into other chemical compounds, we have the only instance of a definite adsorption compound of colloid silver employed as a toning substance. The process possesses an analogy with the formation of the well-known purple gold, or purple of cassius, in which silver takes the place of gold. This compound results when a tin salt in alkaline solution is allowed to act on a silver salt. If stannous chloride is used, the following reactions may be regarded as taking place:

$$Sn + 4\,OH \quad SnO_2 + H_2O \quad 2\,Ag + SnO_2'' = 2\,Ag + SnO_2.$$

The fact that the resulting purple silver actually consists of an adsorption compound of silver and varying proportions of metastannic acid ($SnO_2 + H_2O$) has been shown by L. Wohler,[5] who has ascertained that the purple silver does not contain oxygen in combination.

Whilst as a general rule a coloured colloid silver very readily changes into the coarse grey silver, in the case of this purple silver the metastannic acid acts as a protective colloid against chemical action to such a degree that there is no tendency for the colloid silver to agglomerate. It will, therefore, be understood that the warm colours of deposits (brown to red) are extremely permanent. The particular colour of the purple silver which is formed is, of course, dependent on the structure of the original silver grain.

For the toning of development prints with tin salts, the prints must be first bleached: that is, the silver converted into a colourless and sufficiently soluble silver salt. Neugsch-

2. "Eders Jahrbuch," 1912, 500.
3. "Phot. Korr.," 1913, 503; also "Eders Jahrbuch," 1914, 551.
4. "Photograph," 1920, 89.
5. "Koll Zeitschrift," 7 (1910), 249.

wender recommended conversion into silver ferrocyanide by means of potassium ferricyanide. For this purpose a solution is used containing 150 gms. potass. ferricyanide in 1,000 c.c.s. of water, with addition of 1 c.c. of 25 per cent. solution of ammonia. Neugschwender also mentions that bleaching with copper chloride yields a deeper brown. The copper chloride bath is employed by Desalme and Namias, converting the image into silver chloride. The most advisable formula for this bath is:—

Copper chloride	30 gms.
Hydrochloric acid, sp. gr. 1.12	3 c.c.s.
Water	1,000 c.c.s.

But the colour of the prints or the degree of intensification is not materially affected by the process by which the images are bleached.

The bleached prints must be very thoroughly washed, and are then ready for toning. Toning can be done either separately, by successive action of a tin salt and an alkali, or in one single alkaline bath of tin salt.

In separate toning the caustic alkalies are not suitable, since they attack the gelatine film too strongly. Lime and baryta are also unsuitable, and so is lithium carbonate, on account of its very slight solubility in water. Thus there only remain the carbonates of soda and potash and ammonia (ammonium hydrate). The following are suitable strengths of baths in using these alkalies:—

1 part potass. carbonate in 10 parts of water.
1 part of soda carbonate cryst. in 5 parts of water.
1 part of ammonia, sp. gr. .910 in 20 parts of water.

Since it is difficult to make a clear solution of tin salts in pure water, addition of some acid is necessary. The following solution keeps well:—

Stannous chloride	10 gms.
Hydrochloric acid, sp. gr. 1.12 ...	1 c.c.
Water	100 c.c.s.

If the prints are placed first in the alkali bath and then in the tin solution the results obtained are invariably flat; for vigorous prints it is necessary to immerse first in the tin bath and then in the alkali. After removal from the tin bath prints must be thoroughly washed in order to avoid neutralising the alkali by acid which is carried over with the prints. Unless this is done, the results are erratic and show bad gradation. By washing for a shorter time after the tin bath the colours which are obtained are better, but within a short time the alkali bath is rendered so muddy by tin salt carried into it that it is impossible to work cleanly or to obtain any desired tone with certainty. I find it best to allow the tin bath to act for one or two minutes and the alkali bath for from three to five minutes.

Ammonia yields reddish-brown tones; soda carbonate, brownish-purple tones; and potassium carbonate, intermediate tones. As was to be expected, ammonia, since it is the weakest alkali, yields the finest silver grain; caustic soda yields the coarsest grain, of colour almost approaching a neutral black. But for practical purposes the combined method of toning is by far the better.

For this purpose a bath of sodium stannite is prepared as follows:—A solution is made of 10 gms. stannous chloride (free from acid) in 100 c.c.s. of water, and 70 c.c.s. of 10 per cent. caustic soda solution added with constant shaking until the precipitate first formed is re-dissolved. Water, 80 c.c.s., is then added. A bath of potassium stannite is prepared in a similar way, using, however, 100 c.c.s. of 10 per cent. caustic potash solution and 50 c.c.s. of water for each 100 c.c.s. of 10 per cent. stannous chloride solution.

With bromide prints, the sodium stannite bath yields purple-black tones, whilst the potass. stannite bath gives brownish-black tones. Prints on gaslight papers yield warmer tones, *e.g.*, sepia-brown, resembling the results of platinum toning, with the sodium stannite bath; and a somewhat reddish tone, somewhat recalling that of selenium toning, with the potass. stannite bath.

The combined baths (tin salt and caustic alkali) keep fairly well, especially if always filtered shortly before use. As the substance of the toned image contains only metastannic acid in addition to silver, the prints are extremely permanent, and on this account the process deserves more attention than it has hitherto obtained.

The process of tin toning is applicable also to P.O.P. prints and, with these, allows of effects being obtained which cannot be secured by other methods. It is, of course, plain that P.O.P. prints can be toned by the process only after fixing, otherwise the high-lights and the uncoated surfaces of the prints would be stained yellow or greenish. Addition of stannous salts to the combined toning and fixing bath is out of the question, since it simply gives rise to pronounced sulphur toning. Nevertheless, this method has been both recommended and patented, but can hardly have obtained any use in practice.[6]

If fixed and well washed, P.O.P. prints are placed in a bath of stannous chloride; in the case of collodion prints there is scarcely any perceptible alteration of the colour. Prints on matt-albumen paper, probably in consequence of the fine grain of the image, show a slight apparent effect, especially if the immersed prints are allowed to remain freely exposed to the air, when the adsorbed stannous oxide is converted into stannic oxide. Moreover, there is scarcely any toning action by using a sodium stannite solution. For these reasons attempts were made, as in the case of development prints, to bleach and then to tone. Completely bleached prints, on subsequent treatment with stannous salts, yield very flat gradation with yellowed high-lights, the colour after a short time of toning being red and brown after longer toning. The only satisfactory results were obtained, at any rate with collodion paper, by bleaching incompletely, that is to say, so slightly as to show scarcely any perceptible effect.

I afterwards tried the effect of potass. ferrocyanide as a bleacher, using a solution of 150 gms. per litre diluted 100 times. Prints were immersed in this bath for about a minute and were then toned with the 1:10 stannous chloride solution diluted 20 times, or with the sodium stannite solution diluted 40 times. This process, however, gave prints of inferior reddish-brown tone with eaten-out high-lights.

A more suitable bleacher consists of a copper chloride solution (30 gms. in 1,000 c.c.s.) diluted 20 times. The most suitable toning solution for use with this bleacher is the 1:10 stannous chloride solution diluted 10 times.

The best results are obtained by leaving the prints in the copper bath for not more than one minute, well washing and then toning for one minute in the tin bath. They must then not be washed, but at once hung up to dry in the light. They then darken through formation of metastannic acid with considerable increase of the deposit of purple colloid silver. Subsequent washing does not alter the tone, but is unnecessary, as the unwashed prints are as permanent as those which have been washed.

It was thought that, owing to the fine grain of prints on print-out papers, stannic salts would have an appreciable action on unbleached prints, but it was found that a bath of stannic chloride is almost without effect on the tone of unfixed prints provided that, in order to avoid the slightest trace of sulphur toning, the print is thoroughly washed between use of the tin bath and subsequent fixation. Stannic chloride has an even smaller effect on the tone of fixed prints; and sodium stannate, prepared from stannic chloride and caustic soda, is equally weak in its action. On the other hand, a certain toning action takes place with fixed matt-albumen prints. It may be assumed that the following reaction takes place:—

$$Ag + SnCl_4 + 2\,H_2O \longrightarrow (Ag + SnO_2 + 4\,HCl).$$

The hydrochloric acid evaporates on drying the prints.

A better toning action was obtained with the following

6. "Eders Jahrbuch," 1913, 423.

bath:—10 gms. of commercial "tin salts" (sodium tin chloride $Na_2SnCl_4H_2O$) was dissolved in 100 c.c.s. of water and ammonia added (about 7 c.c.s. of solution of sp. gr. .910), so that the mixture remained slightly acid, without smell of ammonia, and clear after a quarter of an hour. This bath, unlike the more acid solutions, has no eating-out effect on matt-albumen prints; it has an appreciable toning action, though not a great one.

In practical work the use of gold in the purple colloid form is of more importance. Toning baths containing gold in admixture with tin salts have long been recommended.[7] The modern self-toning collodion papers, containing a considerable quantity of gold, are very suitable for toning with tin salts. By using the above mentioned "tin salts" bath instead of the customary bath of salt, reddish-brown tones are obtained with distinct intensification of the print.

By adding potassium bromide, or potassium iodide, to the bath the tone becomes bluer,[8] and at the same time greater intensification is produced.

The following, however, proved to be the best method for the toning of self-toning collodion papers with the salts. The paper is strongly printed, and is immersed for from 10 to 15 minutes in a 1 per cent. solution of potassium iodide, washed for a short time, and then immersed in the following bath:—

"Tin salts"	10 gms.
Water	1,000 c.c.s.
Ammonia, .910 sp. gr.	7 c.c.s.
Potassium iodide	1 gm.

The potassium iodide is added a quarter of an hour after the previous chemicals have been mixed. This bath must be used freshly prepared; it becomes coloured on keeping with formation of free iodine and then has a prejudicial action on the half-tones of the prints.

The prints are allowed to remain in the bath for 15 minutes, are then washed for 30 minutes in order to remove all traces of soluble tin salts, then fixed for 30 minutes in a 1:10 hypo solution, and finally thoroughly washed in the usual way. In this manner vigorous bluish prints are obtained of a kind which is not obtainable by any other process.

The tone may be made more reddish by using a preliminary sulphocyanide bath[9] containing 1 gm. of ammonium sulphocyanide and 1 gm. of potass iodide in 100 c.c.s. of water. This bath must be used before the above-mentioned solution containing both iodide and "tin salts." If it is used after this latter the blue toning effect of the process is very much less.

PERSPECTIVE IN PHOTOGRAPHS.

[The following article by Mr. Arthur Hammond, in a recent issue of "American Photography," while not offering any fresh treatment of the subject of perspective rendering by the photographic lens, usefully draws attention to considerations which too frequently are lost sight of by photographers of both portraits and landscapes.—EDS. "B.J."]

THERE are two kinds of perspective that concern the maker of pictures, whether he uses a camera and lens or whether brushes, paints or pencils are his chosen media. One is linear perspective and the other is aerial perspective. The former is the one that is generally associated with the term perspective, the latter properly should be considered in the study of values. All of us are familiar with the principles of linear perspective and the convergence of lines to a vanishing point that may be inside or outside the boundaries of the picture. We have, most of us, drawn diagrams in school of a railroad track with the lines of the track and other parallel lines all meeting at a point in the distance, and we have learned to draw the outlines of a cube with the lines converging to a vanishing point. In drawing with a pencil we have to study these things very carefully, no matter whether we are making an architectural plan or a purely decorative picture, for incorrect perspective would be a very obvious defect.

That the lens renders such perspective as this automatically and without any thought on the part of the photographer is the generally accepted idea, but this is only partly true. In one sense the perspective as rendered by a lens (provided the lens is free from distortion and the focal plane is at right angles to the axis of the lens) is correct in that a lens reproduces accurately exactly what is before it and in the field of view. But scientific accuracy is not always in strict accordance with what we imagine correct perspective to be, and the brain is always at work correcting our vision and making objects agree with our ideas of how they ought to look. For example, if we close one eye, thus bringing our vision in line with the camera that has only one lens, and hold up one hand about 12 inches from the other eye, the hand will appear large enough to cover and hide entirely a house or a large tree at some distance from us. If we stand close to a person who is holding out towards us a good-sized fish at arm's length the fish will, strictly speaking, appear to be very large in comparison with the person holding it, and if a photograph is taken from a close view-point with a lens of short enough focal length to include both the fish and the person holding it, we shall get a freak picture which will be strictly accurate but not at all in accordance with our ideas as to the relative sizes of the fish and the person holding it.

The correctness of the perspective as it appears to us depends very largely upon the distance between the lens and the objects photographed, just as it does on the distance between the eye and the objects we see. The closer we are the more violent will the perspective appear. To the eye, a hand 12 inches away actually appears so large as to obliterate a house 500 yards away, and a fish held out close to us actually is so large as to appear out of all proportion, but our brain tells us very emphatically that the hand is just an ordinary sized hand and that the house looks small because it is far off. It also corrects our actual impression as to the size of the fish. But the lens has no brain to work for it; it can only work according to the inexorable laws of optical science.

A short focus lens can include a wide angle of view. That is why such a lens is called a wide-angle lens. But the amount of subject that is included depends, naturally, upon the size of the plate or film that the lens covers. A short focus lens used with a large plate will include altogether more than can be taken in by the eye without turning the head. The amount of subject that can be seen by moving the eyes but without turning the head is included in an angle of about 25 deg., and the comparatively wide angle of about 45 deg. is that which is included by the lens commonly fitted to Kodaks and other cameras. Pictorial workers very frequently use lenses of about twice the usual focal length, a 10-inch lens for a 3¼ × 4¼ plate, for instance, instead of the usually fitted 5-inch lens, and thus they get an angle of view that corresponds very nearly to that of the human eye.

The perspective is governed not so much by the focal length of the lens as by the distance between the lens and the objects photographed, for the focal length of a lens is entirely comparative. A 6-inch lens would be a long focus lens if used to cover a plate only an inch and a half square, but a 6-inch lens used for a 5 × 7 picture would be a wide angle, short focus lens. If we took a picture on a 5 × 7 plate with a 6-inch lens we would get just the same perspective and the image would be just the same size as in a picture on a little 1½-inch plate made with the same lens *if the point of view in*

both instances was the same, but in the larger picture there would be more of the subject included. We could trim the 5 × 7 picture down to 1½ inches, and we would then have just the same picture as was taken with the 6-inch lens on the 1½-inch plate. If we wanted that picture to be 7 inches square we could enlarge it, but in order to get a 7-inch picture direct, *from the same view-point*, we would have to use a lens of longer focal length. We could not get the same result by going closer to the subject in order to make it larger with the 6-inch lens, for that would entirely alter the perspective. To get the same perspective in a large picture or a small one, we must take both from the same view-point. If the view-point is the same, the pictures will be identical as regards perspective, though they may vary in size, according to the focal length of the lens that is used. So we see that the perspective depends entirely upon the view-point, and the size is governed by the focal length of the lens. The reason why this is often misunderstood is that we judge the size of objects in a picture chiefly by the important objects in the foreground without paying much attention to the relative size of these objects and objects in the background. Suppose we are photographing a scene in which there are some trees and a background of distant hills. With a certain lens we can get the trees the size we want them by taking the picture from a certain view-point, but if we were using a shorter focus lens and wanted to get the trees the same size, we could only do that by going closer to them, and that would alter the relative sizes of the trees and the distant hills. In the two pictures taken with the long focus lens and the shorter focus lens, the trees might be about the same as regards size, but the distant hills would be entirely different. They would look smaller and apparently farther away in the short focus picture than in the one taken with the long focus lens.

Correct perspective and pleasing perspective often are thought to be synonymous terms, but, strictly speaking, they are entirely different. Perspective may be correct, but, at the same time, far from pleasing. The "big fish" picture already referred to and pictures of people lying down with their feet towards the camera, showing enormous feet and a very small head, are quite correct, but they are far from pleasing. Such things are what we actually see when we are at close quarters and when we look at things impartially, without paying any attention to what our brain tells us as to how they ought to appear. It is rather hard to do this, because the eye is not able to include as wide an angle of view as can be included by a short focus lens, nor can the eye see clearly at the same time a thing close to it and things farther off. I have just been holding up a graduated ruler about 6 or 8 inches from my eye, and when I am looking at the ruler and can see distinctly the lines and figures on it, the pictures on the wall about 8 feet away are blurred and indistinct. When I focus my eye on the pictures the ruler is blurred. The lens is a more perfect optical instrument than the human eye; it can, when stopped down to a small aperture, focus sharply both near and distant objects. The only way we can see near and distant objects clearly is by looking first at one and then at the other. Then, also, a lens can be made that can include a far greater angle of view than the eye. Without turning the head and without moving the eyeball in its socket, our vision embraces only a very narrow angle of about 4 deg. A wide-angle lens specially designed for working at close quarters can be made to include an angle of 90 deg. The lens usually fitted to cameras for average work includes an angle of about 45 deg.

The agreeableness or otherwise of the perspective is governed very largely—we might say almost entirely—by the points of view from which the picture is taken. To get objects of a reasonable size without going too close necessitates the use of a fairly long focus lens. A lens that would include about the same angle of view as we see ordinarily with our eyes would be a good lens for purely pictorial photography, and a 10-inch lens used on a 3¼ × 4¼ plate would be about right. Then we would get in our picture about the same perspective as we ordinarily see. Of course, it is not always practicable to use a lens of such focal length, and it is quite possible to get pictures showing agreeable perspective with such lenses as are commonly fitted, if the photographer will keep in mind the fundamental fact that perspective is governed entirely by the point of view and that the focal length of the lens determines only the size of the objects in the picture. Suppose we take a picture of a landscape—trees, with some hills in the background—with a 10-inch lens used for a 3¼ × 4¼ inch plate, and we get the trees, say, 2½ inches high. Then the distant hills will look about the same as they appear to us when we look at the scene from about the same point of view as we take to get the trees that size in the picture. Then suppose we take the same scene with a 5-inch lens on a 3¼ × 4¼ inch plate and make the trees the same size, 2½ inches high. We shall find that it is necessary to get a good deal closer to the trees, and we shall find that in the picture taken from the closer view-point, though the trees are about the same, the distant hills are dwarfed and are quite insignificant in size, so that they do not give a true impression of the scene as we remember it. But that is not the fault of the lens; it is due to the change in the view-point. If we were to take a picture with a 5-inch lens from the same view-point as we selected when using the 10-inch lens, we should find that the relative size of the trees and hills would be just the same; both would be smaller, and there would be more of the scene included in the picture, but if that portion of it containing only as much as was included in the 10-inch picture was enlarged to 3¼ × 4¼, it would be exactly the same as the picture made with the longer focus lens.

The important fact to remember with regard to perspective is that the focal length of the lens has nothing to do with it. The perspective is governed entirely by the selection of the point of view, and the focal length of the lens determines only the size of the objects included in the picture. The more distant the view-point, the less abrupt will the perspective be. A comparatively long focus lens, one that embraces only a fairly narrow angle of view, is said to give good perspective, but this is only because with such a lens the photographer is forced to adopt a reasonably distant view-point and is not tempted to get too close in the endeavour to make the objects larger in the picture.

The question of agreeable perspective is even more important in portraiture than in landscape work, for the lack of it is far more noticeable. In making large-sized heads a long focus lens must be used, because if we try to get size by going very close we shall get very unpleasant distortion of the features. The very common complaint that the hands in a portrait look too large is often due to the use of a lens that has not sufficient focal length to enable the photographer to select the best view-point. The lens should never be placed closer than 7 or 8 feet from the subject in making a portrait. If at this distance the picture is too small it can always be enlarged, and it is better to get a small picture that has good drawing and good perspective than a larger one that is distorted.

With regard to aerial perspective, that is something entirely different from linear perspective. It deals with the gradual loss of strength in colour and in light and shade in objects as they recede into the distance. This is a valuable aid to the artist, whether he be a painter or a photographer, in enabling him to impart to his picture the quality of "atmosphere."

Without atmosphere a picture looks flat, and is often uninteresting. The illusion of distance and the suggestion of separation of planes given by atmosphere impart a feeling of depth and spaciousness to a view that makes it more realistic. We get a suggestion of distance from the fact that objects in the distance are smaller in size than nearer objects, but if there is no aerial perspective there can be no suggestion of depth and space, and we do not get a proper separation of the planes.

Picture making is, after all, a means of conveying a suggestion of impressions, and there are certain common-sense

principles that are used as aids in creating illusions. The illusion of depth and space is best conveyed by the distant planes being softer and flatter in tone and having less decided light and shade contrasts and colour contrasts. The veil of atmosphere between our eyes and distant objects has the effect of making a light object appear darker and a dark object lighter, so that it is quite possible that a light object and a darker object both at a distance might both appear to be similar in tone. The photographer can control this to some extent by proper selection of suitable conditions, by the use of the right kind of plate or film and by the right adjustment of exposure and development. It is obvious that unless an atmospheric condition exists in nature at the time the picture is made it cannot be photographed. There are times when the air is very clear and dry and the distance appears unusually distinct and dark in tone. Those are ideal days for mountain climbing and for enjoying extended views from the mountain top, but, for picture making, they should generally be avoided, because at such times the illusion of distance is hard to suggest. The distance under such conditions does not look distant, it is so clear and distinct that it appears to be too near, and a picture made at such a time would be lacking in aerial perspective. As a general rule the early morning or late afternoon in the summer are better times for picture making than around noon. In the early morning especially, the atmospheric effect often is very strongly marked.

The use of the right kind of plate or film often means the use of an ordinary plate instead of one that is orthochromatic, because the ordinary plate tends to increase the atmospheric effect a little. The mist or haze is blue, and is therefore strongly actinic, so a plate that is very sensitive to blue would emphasise the haze, while an orthochromatic plate would represent it more as it really is. An orthochromatic plate does not, as is very commonly supposed, "cut out" the haze, it simply does not exaggerate it. There is some scope here for the photographer to use his own judgment. If the mist or haze already is strong enough, it would not be necessary to increase it, and a correct exposure on an orthochromatic plate with a properly adjusted filter would give the best effect.

With regard to exposure and development and their effect on the representation of atmosphere, the exposure must not be too short nor development too long. Too short an exposure always is a serious fault in photography, and it is especially detrimental to a proper rendering of the softened tones of distant planes. Over-development must be avoided, because it tends to block up and destroy gradation in the high-lights.

Photography is not by any means as mechanical a process as it is often supposed to be; there is a good deal of opportunity to exercise personal control, and a pictorial photographer must become thoroughly familiar with the possibilities of his craft, so that he can avail himself of their aid to the fullest extent.

Owing to the fact that we see things with two eyes while the camera usually has only one, it is sometimes necessary to exaggerate and make the most of atmospheric effect in separating planes. Our stereoscopic vision imparts a roundness and solidity to objects we see, and helps very much in placing them correctly, one behind the other. A stereoscopic photograph is vastly more convincing in this respect than one made with only one lens, so it is often quite permissible and quite necessary for a photographer to accentuate mist or haze in the atmosphere as much as he can. This is another reason why a long focus lens is helpful. Its use enables a photographer to select a more distant view-point, and the greater distance between the camera and the objects photographed necessarily increases the amount of atmosphere.

A suggestion of aerial perspective can also be conveyed by selective focussing, which simply means having the important objects in the foreground a little more sharply focussed than those in the background. This tends to make such objects stand out more clearly and helps to separate the planes. If a semi-achromatic lens is used intelligently it will help even more in separating planes, because it can be so manipulated that the quality of definition will vary in the foreground, the middle distance and the distance, and yet there need not be any part of the picture that is so much out of focus as to lose form and coherency and become so much blurred as to be entirely meaningless.

ARTHUR HAMMOND.

THE ABSORPTION OF LIGHT BY TONED AND TINTED MOTION PICTURE FILM.

A communication from the Research Laboratory of the Eastman Kodak Company.

(*Concluded from page* 750.)

In fig. 5 are shown the results obtained on samples 30 and 31, namely, cine green No. 2 (A) and (B). In this case it will be noted

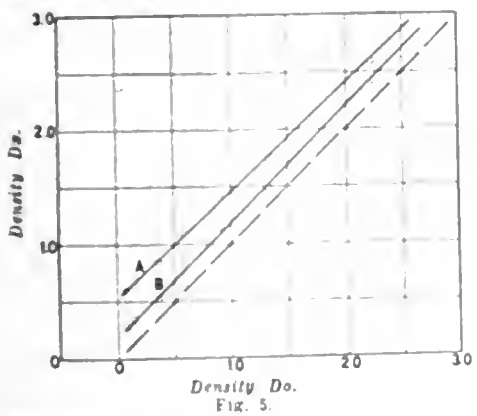

Fig. 5.

that the curves are (to within the errors of measurements) straight lines parallel to the line at 45 deg. to the X axis, indicating that in this case no measurable change in the photographic quality other than the uniform increase in density has resulted from the action of the tinting dye. The curves shown in figs. 4 and 5 are typical of those obtained on all of the samples thus far examined, the cine orange and cine yellow samples behaving as shown in fig. 4, while all other tints appear to behave as shown in fig. 5.

In preparing the tinted samples the following dyes were used, the figures given being the amounts of the various dyes per 200 litres of water.

Tint.	Amount. Grams.	Name of dye and manufacturer.
Cine red ..	.. 250	Amaranth (H. A. Metz & Co., N.Y.)
Cine scarlet	.. 250	Crocein scarlet (MOO) (National Aniline and Chemical Co., N.Y.)
Cine orange	.. 250	Wool orange (GG) (National Aniline and Chemical Co., N.Y.)
Cine yellow	.. 250	Wool yellow, extra conc. (National Aniline and Chemical Co., N.Y.)
Cine green, No. 1	400	Acid green (L) (National Aniline and Chemical Co., N.Y.)
Cine green, No. 2	400	Naphthol green (B conc.) (White Tar Aniline Corp., 56 Vesey St., N.Y.)
Cine blue ..	250	Direct blue (5B) (Essex Aniline Works, 39, Oliver St., Boston, Mass.)
Cine violet ..	250	Fast wool violet (B) (National Aniline and Chemical Co., N.Y.)

Transmission of Dye-Toned Samples.

In colouring film by this process, the positive is bleached in a suitable bath and then immersed in a solution of the dye being used. This dye is mordanted to the image, thus producing the dye tone. Samples were prepared in exactly the same way as for the dye tinting process, an unexposed, fixed-out sample, a normal picture, and a sensitometric strip being prepared in each case, and all tests run in triplicate. The results obtained with the fixed-out sample and the picture are given in Table 2. It will be noted that the transmission of the unexposed, fixed-out samples is uniformly high for all samples. This is typical of this process, since very little mordanting of the dye occurs, except where there is a bleached silver image. Since these samples were unexposed, the only silver present was that due to the inherent fog of the material, which is relatively low, so that in these samples very little bleached image is present upon which the dye may be mordanted.

Table No. 2.—Transmission of Dye Toned Film.

Sample.	Name.	Plain film. D.	Plain film. T.	Plain film. T_r.	Picture. D.	Picture. T.	Picture. T_r.

9	Bismark brown	0.17	67	76	0.96	10.9	75
12	Malachite green (A) ..	0.16	69	78	1.10	8.0	55
10	Malachite green (B) ..	0.17	67	76	1.12	7.6	52
11	Malachite green (C) ..	0.18	66	75	1.15	7.0	48
15	Safranine (A)	0.18	66	75	1.00	10.0	69
14	Safranine (B)	0.18	66	75	1.03	9.0	62
13	Safranine (C)	0.18	66	75	1.20	6.3	43
18	Auramine (A)	0.15	71	81	0.86	14.0	96
17	Auramine (B)	0.16	69	78	0.90	13.0	89
16	Auramine (C)	0.16	69	78	0.93	12.0	83

In fig. 6 are shown the measurements obtained on one of the sensitometric strips dye-toned with Malachite green. It will be

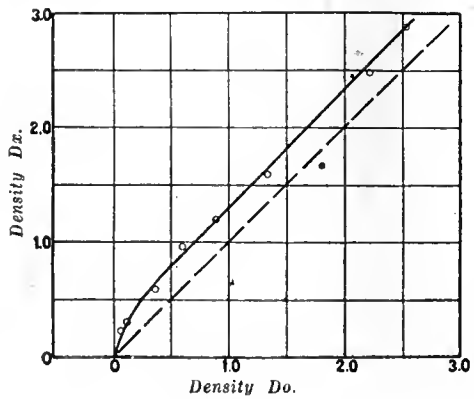

Fig. 6.

noted that in the region of higher densities that the curve is parallel to the 45-deg. line, thus indicating that in this region the increase in density is independent of the original density, but in the regions of lower density this is not the case, as is indicated by the curve in fig. 6. The high-light regions, therefore, suffer less intensification than the shadows and darker half-tones. It is evident that such action results in increased contrast in the dye-toned positive. The results illustrated in fig. 6 are typical of the other dye-toned sensitometric strips that have been examined thus far.

Transmissison of Chemically-Toned Samples.

Complete discussion on the methods for obtaining these chemical tones have been referred to earlier in this communication, and no attempt will be made at this time to specify the exact processes by which the samples examined were prepared.

Detailed directions may be found in the booklet referred to or in the "Motion Picture News," as follows:—Sulphide, Tone F, page 3580, 1918; iron, Tone H, page 3580, 1918; uranium, Tone B, page 3411, 1918. The variants A, B and C were obtained by changing the times of toning.

The results obtained with the unexposed, fixed-out sample and the normal picture are given in Table 3, the values of the various columns being analogous to those in the previous tables. It will be noted in this case also that the transmission of the unexposed fixed-out sample is in all cases very high, approaching in some cases that of the untoned sample. In the case of this method the colouring is very slight in those regions of low photographic density, the effect increasing as the amount of silver present increases. The transmission values of the normal picture, it will be noted, are in general somewhat low, this indicating that films prepared by this method will in general be of high density and require a considerable increase in the intensity of the projecting light in order to produce pictures of normal brilliancy.

Table No. 3.—Chemically Toned Film.

Sample.	Name.	Plain film. D.	Plain film. T.	Plain film. T_r.	Picture. D.	Picture. T.	Picture. T_r.
0	Untoned	0.055	88	100	0.84	14.5	100
19	Sulphide	0.14	72	82	1.00	10.0	69
22	Iron	0.09	81	92	1.04	9.1	63
21	Iron	0.09	81	92	1.15	7.1	49
20	Iron	0.10	79	90	1.17	6.7	46
24	Uranium	0.14	72	82	1.01	9.8	68
25	Uranium	0.15	71	81	1.07	8.5	59
23	Uranium	0.15	71	81	1.17	6.7	46

In fig. 7 are shown graphically the results of the measurements obtained on one of the sensitometric strips toned by the iron process. In this case the lack of proportionality in the increase of density is even more marked than in the case of the dye-toning process shown in fig. 6. It will be noted that there is a very slight

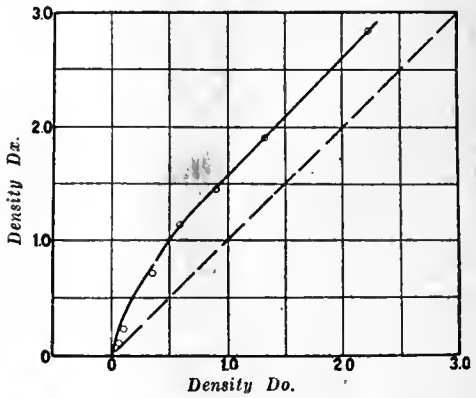

Fig. 7.

increase in the density of the high-light region, while the increase in density in the case of the higher densities is very marked. Here again the curve for the region between densities of .6 and 2.6 is practically parallel to the 45 deg. line, showing that in this region intensification is proportional, while for densities of less than .6 this is not true. Such an action of the chemical toning process produces a marked increase in the contrast of the positive, and undoubtedly results in a considerable change in photographic quality of the pictures thus treated. The behaviour, as illustrated by the curve in fig. 7, is typical of all of the toning chemical processes thus far examined.

Mean Transmission of Cinematograph Positives.

The question has frequently been raised as to the average transmission of various types of cinematograph positive. Since it is quite easy with the apparatus developed for the study of toned and tinted film to measure the mean or average transmission of such films, it was decided to select a group covering the entire range of subjects as completely as possible, and to measure the mean transmission of these films. From a stock of positives 41 different pictures were chosen, and the mean transmission values of each determined. In Table No. 4 are given the results of each measurement, and it will be noted that the highest transmission is 38.8 per cent., while the lowest is 3.2 per cent., the mean of the 41 being 14.5 per cent. It was interesting to note the coincidence occurring between the mean of this group and the particular picture chosen for making the toned and tinted samples. In order to convey a more concrete idea as to the mean transmission of various types of subjects, 6 of these are reproduced in fig. 8. Below each picture is the identification number with the mean transmission

value for the positive. We are indebted to Mr. Thomas H. Ince and to the Goldwyn Corporation for the original negatives from which these illustrations are made.

Average transmission	.. ..	14.50 per cent.
High transmission (No. 39)	.. ..	38.8 ,,
Low transmission (No. 29)	.. .	3.2 ,,

Summary.

An instrument suitable for the measurement of the transmission of toned and tinted motion picture film has been designed and constructed, and a satisfactory method for the measurement of the desired values worked out.

A large number of samples of toned and tinted film have been prepared and their transmission determined.

Results indicated that in the case of dye tinting no appreciable change in the photographic quality is produced, and while the transmission may vary over a wide range, depending upon the precise treatment, that in general the transmission is fairly high.

The various processes of dye toning in general produce a slight distortion in the photographic quality, this being in the direction of increasing the contrast especially in the region of the lighter half-tones.

Chemical toning processes also tend to produce some change in photographic quality, this also being in the direction of enhanced contrast.

The mean transmission of a representative group of positives has been measured, and the average found to be 14.5 per cent.

The authors wish to acknowledge their indebtedness to Mr. J. I. Crabtree for his co-operation in this work, and to Mr. Delos Rupert, who prepared all of the toned and tinted samples upon which measurements were made.

PHOTOGRAPHIC RAW PAPER BASE.

OPENING OF MESSRS. PIRIE'S ABERDEEN MILL.

ON Wednesday in last week, December 14, an interesting ceremony took place at Bucksburn, Aberdeen, when the new mills erected by Pirie's Photographic Paper Co., Ltd., were formally opened in the presence of a large company, which included Mr. E. D. Pirie, chairman of the parent firm of A. Pirie & Sons, Ltd., and Mr. A. H. Starnes, managing director of Pirie's Photographic Paper Co., Ltd. We are indebted to the Aberdeen press for the following account of the new enterprise.

The new paper mill has been designed and erected specially for the manufacture of photographic base papers, and marks another stage in the endeavours of this firm to establish a new British industry. Although British firms have always been pre-eminent in the manufacture of sensitive photographic materials, the base paper used had, previous to the war, been imported from the Continent, and, in fact, in 1914 there were only four or five mills in the world which had made a success of the manufacture of these base papers. As the most of these mills were in Germany, the whole photographic trade of the country was, naturally, at the outbreak of war, completely cut off from the source of supply of base papers.

Owing to the fact that photography, and more especially aerial photography, proved to be essential in warfare, the Government approached several papermakers—amongst them Alex. Pirie & Sons, Ltd.—with a view to getting them to undertake the manufacture of base papers, and this firm, who had been experimenting with these papers for several years previously, decided to make a big effort to capture the trade for this country. It was quickly realised that, to make a complete success of the manufacture, a new mill designed especially for the purpose was essential, but as the matter was so urgent, an endeavour was made to manufacture paper as a temporary measure in the present mill, a considerable portion of the machinery and plant being re-designed and altered for the purpose.

The results obtained, while not at first equal in purity and quality to the pre-war Continental makes, nevertheless showed considerable promise, and as experience in the manufacture was obtained improvements were constantly being made, so that at the present time many grades of paper are manufactured that bear comparison with present-day Continental makes. The amount of research work necessary to bring the paper to this standard in such a short time, and under such difficult conditions, was naturally enormous, and it was found necessary in 1917 to form a subsidiary company, which is known as Pirie's Photographic Paper Co., Ltd., and which has, since that date, been responsible for the manufacture and sale of these photographic base papers. This change had the advantage that the scientific and technical staff were in a position to give their undivided attention to the manufacture, testing and improvement of these papers.

Although it was found possible during the war period to manufacture more than 3,000 tons of photographic base papers with the existing plant, it was always realised that this was to be looked upon only as a temporary expedient, and designs for a completely new mill were proceeded with as quickly as possible. Building on the large scale required was, of course, impossible during the war, so that it was not until early in 1920 that the construction of the new mill started. This mill, which is now complete, is a steel-frame building filled in with brick and continuous steel windows, and has reinforced concrete floors and roofs throughout. The total length of the buildings is about 850 ft., while the floor area amounts to 20,500 square yards, or over four acres.

The first thing that strikes the visitor is the extraordinary precautions that have been taken to prevent the slightest possibility of the product being contaminated with dirt or other impurities. The whole of the buildings are practically dust-proof, filtered air only being admitted, and special rooms are provided for any machinery likely to cause dust. Metal has been replaced at almost every stage

by other materials or covered with substances that have no harmful action, and, wherever possible, tanks and other containers have been lined with tiles.

The manufacture of photographic base papers has always been recognised to be a particularly difficult one, and it has been found necessary to equip very large and elaborate research laboratories, together with a complete chemical and physical control plant, so that every consignment of paper may be tested on a practical scale before dispatch to the customer. By these means, and aided by scientific control throughout, it is hoped that the manufacture of these photographic base papers will be brought to such a standard of perfection that this country will in future be independent of Germany for supplies of raw materials.

Machinery for this new mill has been obtained from Messrs. James Bertram & Son, Ltd., Edinburgh, the electrical equipment from Messrs. Mather and Platt, Manchester, while the buildings have been designed and erected under the supervision of Messrs. Jenkins and Marr, civil engineers and architects, Aberdeen. It is understood that the total cost of the mill, when fully completed, will amount to between £300,000 and £400,000, and that it is the only mill in the country which undertakes the making of the base paper and also the baryta coating, and so prepares the paper that it can be taken in hand by the sensitising firms without further treatment.

Nine hundred and fifty tons of structural steel, 2,200 tons of Portland cement, and 1,400,000 bricks were used in the construction, while the roofs, which are made of reinforced concrete, covered with rock asphalt, have an area of nearly 10,000 square yards.

FORTHCOMING EXHIBITIONS.

1922.

January 11 to 27.—Camera Portraits, entitled "Men of Mark," by Walter Stoneman, at the house of the Royal Photographic Society, 35, Russell Square, London, W.C.1.

January 21 to February 4.—Partick Camera Club. Particulars from the Hon. Secretary, James Whyte, 51a, Peel Street, Partick, Glasgow.

February 11 to 25.—Scottish Photographic Salon. Latest dates, entry forms, January 23; exhibits, January 31. Particulars from the Secretary, James F. Smellie, Braefindon, Allanshaw Street, Hamilton.

February 14 to 17.—Exeter Camera Club. Latest date for entries, January 30. Particulars from C. Beauchamp Hall, Hon. Exhibition Secretary, Exeter Camera Club, "St. Denys," Bellevue Road, Exmouth.

February 18 to March 4.—Edinburgh Photographic Society. Latest dates, entry forms, February 4; exhibits, February 9. Particulars from the Hon. Secretary, G. Massie, 10, Hart Street, Edinburgh.

March 8 to 9.—Birkenhead Photographic Association. Latest date for entries, February 25. Particulars from the Exhibition Secretaries, Messrs. Longstaff and Trace, 33, Hamilton Square, Birkenhead.

THE LATE M. A. VILLAIN.—We are sorry to see the announcement of the death of M. Villain, a French textile chemist who took a great interest in photographic processes. He was the inventor, about 1892, of a process of printing on fabric, sensitised with a mixture of bichromate and a vanadium compound, followed by dyeing of the mordanting image thus produced. Several articles on this subject were contributed by him years ago to the "Photogram." He was also the originator of a photographic method of preparing cylinders for textile printing.

DEATH OF DR. MEYDENBAUER.—The death is announced of Dr. A. Meydenbauer, a pioneer in photogrammetry and at one time head of the photogrammetric institute established by the Prussian Ministry of Education. Dr. Meydenbauer was the author of numerous papers describing the application of a camera to the making of true scale records of buildings. He appears also to have been one of the first to employ the system of developing plates for a long time in a weak developing solution—the so-called stand development.

Patent News.

Process patents—applications and specifications—are treated in "Photo-Mechanical Notes."

Applications December 5 to 10 :—

CAMERAS.—No. 32,700. Photographic cameras. A. J. Denniss, V. W. Edwards, and Houghton-Butcher Manufacturing Co., Ltd.

APPARATUS.—No. 32,819. Photographic apparatus. E. E. Fournier d'Albe and F. W. Warrick.

COLOUR STEREOSCOPY.—No. 32,810. Taking and projecting stereoscopic colour photographs. A. W. Wyatt.

CINEMATOGRAPHY.—No. 32,972. Apparatus for taking cinematograph views. A. de Brayer.

CINEMATOGRAPHY.—No. 32,942. Cinematograph apparatus. E. N. and J. E. Thornton.

CINEMATOGRAPHY.—No. 32,941. Cinematograph apparatus. H. M. Thornton.

COLOUR CINEMATOGRAPHY.—No. 32,631. Colour cinematography. D.C.L. Syndicate, Ltd., and F. W. Donisthorpe.

CINEMATOGRAPH-PHONOGRAPH.—No. 32,692. Method of synchronising gramophone with cinematograph. J., J. T., and W. F. Bruce and Bruce Patents Corporation.

CINEMATOGRAPH-PHONOGRAPH.—No. 33,092. Means for projection of cinematograph pictures and reproductoin of sounds synchronously therewith. H. B. and H. R. Stocks.

COMPLETE SPECIFICATIONS ACCEPTED.

These specifications are obtainable, price 1s. each, post free, from the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C.

The date in brackets is that of application in this country; or abroad, in the case of patents granted under the International Convention.

PORTRAIT LENSES.—No. 165,664 (June 28, 1920). The invention relates to improvements in photographic objectives, more particularly portrait lenses, comprising a single front lens and a compound back lens composed of a negative flint glass lens cemented to a positive crown glass lens.

It is the primary object of the invention to provide a photographic objective which combines high working speed with great depth of focus and good definition.

Another object is to produce an objective which, apart from the properties just mentioned, has the advantage of light weight and cheapness and is of general utility.

In the drawing I represents the front lens. The back lene is made up of a biconcave negative II and a biconvex positive III, forming together a fully achromatic lens. When used with an uncorrected front lens it is sufficiently corrected for practical purposes.

The front lens is a thin meniscus positive whose focal length is from three to ten times that of the back lens and whose diameter is about 50 per cent. to 60 per cent. larger than the diameter of the back lens.

While there is, of course, considerable latitude, an objective of the following characteristics may be considered as representative of the invention.

1 Front lens	
$r1 = 183.40$	$D = 1.5170$
$r2 = 261.10$	$\gamma = 54.3$
II Biconcave of back lens	
$r3 = 9017.00$	$D = 1.626$
$r4 = 288.40$	$\gamma = 36.6$
III Biconvex of back lens	
$r5 = r4 = 288.40$	$D = 1.517$
$r6 = 159.25$	$\gamma = 54.3$
$d1 = 5.5''$	$F1 = 56''$
$d2 = 4.75''$	$F2 = 18.7''$
	$E = 15''$

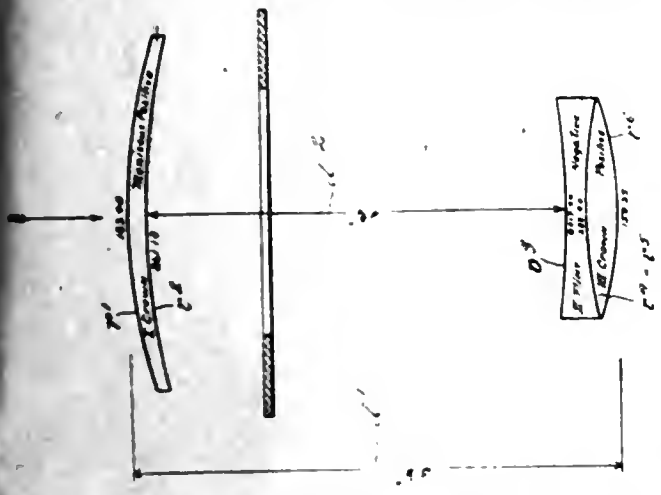
wherein r refers to radius of curvature, D to index of refraction, γ to power of dispersion, F1 to focal length of the front lens, F2 to focal length of the back lens and E to equivalent focal length of the combination.

All principal corrections are made on the back lens. Since this lens is relatively small, the quantity of expensive glass required

is small. The larger front lens may be of inexpensive glass. The cost of the objective is therefore relatively small.

By combining the highly corrected back lens with the uncorrected front lens, the disadvantages of the two neutralise each other. The aberrations in the front lens preclude the formation of a critically sharp image in a single plane. The blending of the circles of confusion of different size brings about greater depth and softness and yet of good definition. It is not necessary to stop down in order to obtain greater depth of focus, as with the present standard forms of portrait lenses for close range work, or to improve the definition as with the so called pictorial lens which with full aperture lacks that degree of definition required for portrait work.

Curvature of field and distortion are overcome by the long focus front lens of slight convexity. By the slight convexity of the front lens the virtual object plane is flatter and the rays are more uniformly and gradually brought in and focussed more



evenly on the plate than could be done with the customary front lens of shorter focus and of greater convexity.

By using a shorter focus rear lens (1/10 to ¼ of the focal length of the front lens) and of comparatively smaller diameter (approximately 65 per cent. of the diameter of the front lens) the rear nodal plane of the combination is brought near the rear lens whose aperture then acts partly as a diaphragm opening.

The nearness of the back lens to the rear nodal plane and its small size make it possible to use a larger stop which allows more light to pass in from the front lens and thereby affords a greater practical working speed. The slender light cones coming through the long-focus thin front lens reach the rear lens with greater actinic power than would be possible if the larger angle light cones collected through shorter focus front lenses of smaller diameter were reduced by cutting out the marginal rays by means of the stop. A reduction of the source of light whether by the front lens or diaphragm opening reduces the amount of light reaching the rear lens.

It is understood that the focal length of the front lens may vary within wide limits. The equivalent focal length of the combination may consequently be changed by merely using front lenses of different focal lengths, but in no case is the distance between the front and back lenses less than one-fourth of the focal length of the combination.—Lloyd Cassel Bishop, 508, Dean Building, South Bend, County St. Joseph, Ind., U.S.A.

Envelope Plate-Holders.—No. 156,564 (January 2, 1920). The invention relates to a protecting layer of paper designed to protect the emulsion-coating of photographic plates during the exchanging of the plates in a daylight change-packing. When the plates are being changed it happens frequently that the emulsion-coating gets injured when sliding along the succeeding plate or the lid. To avoid this, a protecting layer adapted to move with the photographic plates is inserted between the plates.

In the drawings the protecting layer (fig. 1) is preferably made from paper sheets piled up in a convenient manner to be cut or stamped into the proper shape.

Every single protecting layer 1 is folded so that at one end a triangle 2 is formed through the corners having been folded over along the dotted lines 3, 4, the edge 3—5 being placed along the imaginary line 3—6 which corresponds with the edge of the photographic plate. The gummed small triangle 7 is then folded along the line 6—8 and glued together with the corner 5 of the triangle 2, whereby a slitlike opening is formed between the lines 3—6

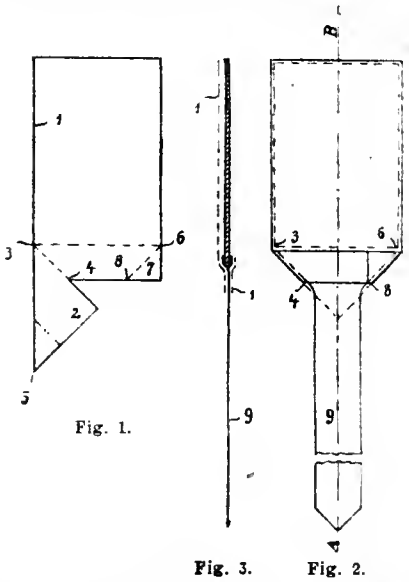


Fig. 1. Fig. 3. Fig. 2.

and 4—8, similar to a pocket into which the enlarged part of the change-strip 9 can be inserted.

In order to protect the emulsion-coating 11 of a photographic plate 10 during the changing and moving in a changing-box, the protector 1 (fig. 5) is placed with its pocket over the upper edge of the plate 12. Through the pocket the change-strip 9 is pulled which, as indicated in figs. 5 to 7, moves with the plate 10 attached to the same over the protecting layer 1 until the plate 10 stands over the plate 12. From now on (as shown in fig. 7) the plate 10 with the protecting layer 1 is pulled down by means of the change-strip 9 in the direction of the arrow, the emulsion-

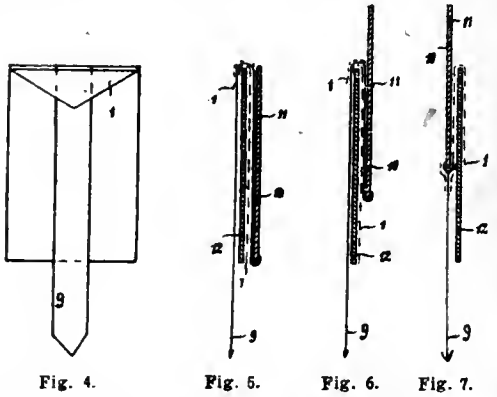

Fig. 4. Fig. 5. Fig. 6. Fig. 7.

coating 11 being well protected against scratching and injury owing to the protecting layer 1 which moves with the plate.

There can be changed in this manner any number of photographic plates with protecting layers stored up in a change box.—Michael Lesjak, F361, Oberes Kreuz, Augsburg.

The following complete specifications are open to public inspection before acceptance :—

Film Coating.—No. 172,280. Coating of photographic films, paper and so forth. Kino-Film Co. and C. Münch.

Trade Names and Marks.

APPLICATIONS FOR REGISTRATION.

Tintona.—No. 416,795. Photographic sensitised paper. The Leto Photo Materials Company (1905), Ltd., 1, Crutched Friars, London, E.C.3, photographic manufacturers. July 8, 1921.

New Books.

American Annual of Photography, 1922. Edited by Percy Y. Howe. New York: George Murphy, Inc., 57, East Ninth Street. 1.75 or 2.5 dollars.

THE "American Annual" occupies a place by itself among photographic publications by providing year by year an interesting miscellany of articles on current practical topics and by bringing together reproductions of photographs, creating or maintaining interest in different branches of work. Carroll B. Neblette leads off the articles with a review of progress during the present year, and it is notable that the items which he signalises are almost all of them of British origin, namely, the Impex X-ray plate, the Dye Impression process, the Carbine film tank and the D.50 developer. Other contributions touch upon such subjects as soft-focus *V* anastigmat lenses, stereoscopic photography, Bromoil, Kallitype, darkroom illumination, multiple gum, outdoor portraiture and the optics and mechanics of enlarging. A contribution of special interest is that by J. I. Crabtree, describing a systematic photographic series of tests for ascertaining the comparative value of developing substances. The volume contains a list of American photographic societies, admitted to be incomplete, and a collection of the formulæ for developers, fixers and toners most commonly in use in the United States. The illustrations are well printed, many of them as supplemental plates, but better advantage could be taken of the expense incurred in their inclusion by a higher standard in the choice of originals.

THE CHEMIST AND DRUGGIST DIARY, 1922.—In addition to the diary proper, this handsome volume, issued by our contemporary, "The Chemist and Druggist," 42, Cannon Street, London, E.C.4, contains working particulars of the present legislation respecting poisons, national insurance, Excise duties, etc., affecting pharmaceutical chemists. Another large feature of the volume is the directory of the chemical trade and the corresponding highly classified index to the suppliers of the hosts of chemical substances and proprietary articles on the market. This compilation and the very numerous advertisement pages together provide a most complete source of reference to the chemical trade.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK.

MONDAY, DECEMBER 26.

Walthamstow and Dist. P.S. "Enlarging." E. Willcocks.

TUESDAY, DECEMBER 27.

Hackney Phot. Soc. Chat Round the Fire.
South Glasgow Camera Club. "Finishing and Mounting the Exhibition Prints." A. T. Edgely.

WEDNESDAY, DECEMBER 28.

Accrington Camera Club. "How a Reflex Camera is Made." Miss B. Willian.
Croydon Camera Club Conversational Evening.
Dennistoun Amat. Phot. Assoc. "Stereoscopy." R. Rochead.
Forest Hill and Sydenham P.S. "Lantern Slide Making." C. H. Summers.
Rochdale Amateur P.S. Members' Lantern Slides.

THURSDAY, DECEMBER 29.

North Middlesex P.S. "Carbro." A. Dordan Pyke.

FRIDAY, DECEMBER 30.

Walthamstow and Dist. P.S. "Flashlight." A. Dordan Pyke.

ROYAL PHOTOGRAPHIC SOCIETY.

Meeting held Tuesday, December 20, the president, Dr. G. H. Rodman, in the chair.

Mr. C. Ralph C. Petley delivered a lantern lecture on "The Chamounix Valley," in which he described, with many admirable illustrations, the scenery of this famous part of the Alps, noted for its many views of Mont Blanc. On the proposition of the chairman a hearty vote of thanks was accorded to the lecturer.

CROYDON CAMERA CLUB.

Mr. C. P. Crowther would have paid a visit with a portable lamp for portraiture had the electric fluid been once again on tap, which was not the case, owing to a wholesale condemnation of the wiring by some fussy inspector. So in order to console all for the disappointment the secretary convened a special uplifting meeting for the purpose of raising the subscription.

It appears that the club's landlord, the Phœnix Assurance Co., true to the Egyptian tradition of its fabulous birth, is once again raising an improved rent out of the ashes of the old. To add to tribulations, a small tract society, who hired the club rooms one day in every week, can no longer afford to do so, and has left, harmonium, hymns, and all. Alas, and alack! has departed the spiritual once-a-week atmosphere which permeated the walls, and passers-by no longer look upwards attracted by pious strains descending. The harmonium, too, is missed, as it used to form an ecclesiastical background to the bar, emphasising Chesterton's "Christian touch."

As the treasurer, Mr. Ackroyd, rose, many must have conjectured things had arrived at a parlous state owing to his depressed expression, luckily merely due to a transient bilious attack. In a masterly way he disgorged himself of a mass of facts and figures, and appeared much relieved in consequence. Unanimously it was agreed to raise the subscription from half a guinea to fifteen shillings. Mr. B. J. Rose pointed out that the higher the subscription, in all probability, the better the attendance, as members would realise they would be losing their money's worth if they failed to turn up. Just a little bit optimistic is Mr. Rose.

Some experiments by Mr. Sellors on a diffusing device were then brought forward, any reference to which is postponed.

GLASGOW AND WEST OF SCOTLAND SOCIETY OF PROFESSIONAL PHOTOGRAPHERS.

Mr. C. P. Crowther, F.R.P.S., lectured to members of this Society and their friends in the Glasgow School of Art, on December 13, on "Psychology in the Studio." Mr. J. R. Brinkley, President of the Society, occupied the chair.

Mr. Crowther dealt with the photographer's work in handling sitters in the studio, and insisted that only by repetition could they reach perfection and gain the command of their materials. Unless they could perform all the essential operations subconsciously they would not do them well. If they had to stop to consider all the details they would probably lose the picture. Pictorial portraiture was now being insisted upon and largely patronised by certain classes, but there were still others who wanted the orthodox picture that had been taken for so many years. He hoped the time was coming when people would like to see pictures in which they really looked like human beings. There were more people than even many photographers realised who liked to be depicted as they are. The lecture was illustrated by a number of lantern slides of Mr. Crowther's portrait work, several of which have been exhibited at this year's Salon.

At the close of the lecture, which was highly appreciated by the audience, Mr. A. Fairbairn expressed the great pleasure it had given the members to listen to Mr. Crowther's able and instructive lecture, and the deep debt of gratitude he had placed them under by coming to Glasgow to lecture to them, and on his motion the audience accorded Mr. Crowther a very hearty vote of thanks.

EDINBURGH SOCIETY OF PROFESSIONAL PHOTOGRAPHERS.

Mr. C. P. Crowther, F.R.P.S., London, delivered an interesting lecture on "The Psychology of the Studio" to the members on Monday, December 12. There was a large and appreciative audience.

At the outset, Mr. Crowther gave a number of valuable hints to photographers on the best methods of carrying on their business, the keynote of which was to avoid as much as possible the getting into "a rut." He spoke of the different ways of handling sitters, and said that the actions and conversation of the photographer and the easy manner in which the tactful operator did his work contributed to a large degree to his success in obtaining a correct expression.

Mr. Crowther further dealt with the lighting of the sitter, and showed excellent examples by lantern slides and prints illustrating the various methods now used. He strongly recommended the use of the three-quarter, or angle 45 deg. lighting, as being the safest, and from which the best results for general work were obtained. He showed examples of work done at home with one small half-watt lamp—the operator held the light in his hand and "painted" the face with the light, *i.e.*, he moved the light over the face as his judgment directed, giving an exposure of five to seven seconds at 45 degrees. The results were excellent and perfect modelling was secured.

Mr. Crowther also showed examples of large whole-plate heads done with a 12-inch lens, the head almost filling up the plate and showing no apparent distortion. The ears and top of the hair being out of focus was, in Mr. Crowther's opinion, an advantage.

A discussion took place regarding lighting and short-focus lens work.

Mr. Campbell Harper, the President of the Society, moved a cordial vote of thanks to Mr. Crowther for his inspiring and delightful lecture, which was heartily responded to by the audience.

PROFESSIONAL PHOTOGRAPHERS' ASSOCIATION.

A meeting of the Council was held at 35, Russell Square, on Friday, December 9, 1921. There were present: Messrs. Marcus Adams, A. Basil, A. Bennett, Frank Brown, W. B. Chaplin, H. Chapman, G. Chase, T. Chidley, A. Corbett, C. Dickinson, A. Ellis, R. Haines, G. Hana, W. Illingworth, H. Lambert, H. A. St. George, R. N. Speaight, F. Wakefield, H. Wheeler, and Lang Sims (Secretary). Mr. Alfred Ellis in the chair

Apologies for absence were read from Mr. Swan Watson (President), and Messrs. W. E. Gray, F. Read, H. C. Spink, and T. C. Turner.

The Secretary reported seven applications for membership, several of which were from Nigeria, through Messrs. Houghton's, Limited. He had made inquiries with regard to these candidates, and had been told that they were mostly small buyers of photographic material, and appeared to be native professional photographers. All the nominations were agreed to.

The Secretary read some correspondence with a country member with regard to photographs of a memorial which he had taken, and which had been made use of in an unauthorised way by two men who travelled about getting orders for enlargements, etc. After some discussion it was agreed that the whole matter should be referred to the solicitor for his advice with regard to a prosecution or other action

Mr. Speaight (as Treasurer) said that all members who were two years or more in arrear with their subscriptions had been written to, with the following result:—Number of registered letters sent, 170; subscriptions paid up, 35; resigned, 21 (of whom 4 paid arrears); promised to pay, 5; no answer, 113. He thereupon read the names of the 113 members from whom no answer had been received and the 21 who had resigned, and moved that they be struck off the list, in accordance with the decision of the previous Council meeting.

It was proposed that the Chairman defer signing this list, thereby authorising the names to be struck off, until the January meeting, but this was lost.

The motion to write off the names was carried, and the Chairman then signed the document, adding that there was no bar to the reinstatement of any of those whose names appeared in it.

Mr. Speaight said that it was gratifying that among the resignations, in not one case was the accusation made that the Association had failed in any action it should have taken, which could have given the member an excuse for resignation.

The 1922 Congress.

The Secretary read the reports of two meetings of the Combined Congress, Finance, and Exhibition Committees *re* 1922 Congress. He added that the written confirmation of the arrangements made with the manager of the Prince's Galleries had now come to hand, and the rooms were booked for the second week in September, 11th to 16th.

Mr. Speaight read the list of sub-committees which it was proposed should undertake the burden of work in connection with the Congress. The names of members suggested for each of the sub-committees were, so far, quite incomplete, for it was hoped to add to them various country members, as well as possibly other London members. But a Secretary or Convener for each sub-committee had been chosen as follows:—

Finance: Mr. St. George.
Trade Exhibition: Mr. Wakefield.
Home Exhibition of Photographs: Mr. Speaight.
Foreign Loan Exhibition: Mr. Adams.
Propaganda and Catalogue: Mr. Haines.
Entertainment: Mr. Ellis.
Musical: Mr. Lambert.
Assistants' Evening: Mr. Chase.
Lanternist Sub-Committee: Mr. Chaplin.
General Congress Committee: The Secretary (Mr. Lang Sims).

Mr. Frank Brown, as a provincial member, expressed the general indebtedness to the initiative of the London members, and said that the country members would co-operate as fully as they were able.

Some general conversation ensued on the advisability of holding the Congress and Exhibition in the early part of September, but Mr. Speaight and others pointed out that the decision of the Council on this point was taken at the last meeting, after a long and exhaustive discussion, when it was explained that this was the only time in the year in which the galleries chosen or any other suitable accommodation would be available. The resolution was carried by a large majority.

Charges for Electricity in the Studio.

The Secretary read a letter from the Westminster Electric Supply Corporation confirming an arrangement come to whereby, although they could not admit that photographers' current supply came in the category of power demand, they agreed to grant a flat rate charge of 4d. per unit (as against 8d. in the past) to take effect from October 1 last.

This announcement was received with much satisfaction, and Mr. Alexander Corbett, by whom the negotiations had been conducted, was highly complimented by the whole Council.

Mr. Corbett refused to take the credit to himself, saying it was largely due to the influence of Mr. Duncan Watson—a personal friend of his own—backed as he was by a representative society, and it was owing to this combination that the concessions had been granted. He hoped that photographers not yet members would take the lesson to heart, and join up without further delay. He pointed out that the stronger the P.P.A. was numerically the greater would be its driving power.

Special General Meeting.

A special general meeting of the members of the Association was held at 35, Russell Square, on Friday, December 9, 1921, at 6.30 p.m., to consider a necessary amending resolution in connection with the incorporation of the Association.

Mr. Alfred Ellis, Chairman of Council, presided. In addition to members of Council a number of other members attended.

The Chairman said that the notice convening the meeting sufficiently explained the reason why this special general meeting was called. The only business was to consider and vote upon a resolution, which he would formally move:—

"That the Council of the Association do construe and act upon the resolution passed at the general meeting on the 22nd April, 1921, as if the words 'not for profit,' which appear in the first paragraph of such resolution, had been eliminated from such resolution or had formed no part thereof, and that the Memorandum and Articles of Association as approved by the Council, be adopted for the purposes of the new Association, and that such new Association be registered under Section 21 of the Companies (Consolidation) Act, 1908."

Mr. Stoll Bailey (Putney) seconded the resolution.

On being put from the chair, it was carried unanimously.

The Chairman thanked the members for their attendance, and said that though no more formal business could be taken he would be glad to hear anything which any visitor had to say with regard to Association policy.

Mr. T. F. Nicholson (Ealing) said that the members, he felt sure, had unbounded confidence in their officers, and he had made

a point of attending to voice his appreciation of the work of the Council in the interest of their fellow professionals.

The proceedings then closed.

FOREST HILL AND SYDENHAM PHOTOGRAPHIC SOCIETY.—At the meeting on December 14, Mr. H. G. Fleck gave an instructive demonstration on gaslight printing for the benefit of beginners. He showed that by immersing the print in a weak solution of glacial acetic acid between development and fixing stains could be avoided and at the same time development arrested. After making a number of prints, the demonstrator invited a new lady member, who had never made a gaslight print, to try her hand, which she did quite successfully. The meeting on December 29, at Christ Church Schools, Forest Hill, will be devoted to lantern slide making, the demonstrator being Mr. C. H. Summers, a member whose slide gained for the Society the highest award in the Affiliated Societies' competition in 1914. The Society is making a special feature of helping beginners, and a large influx of new members has been in evidence recently. Local unattached photographers will be warmly welcomed as members

Commercial & Legal Intelligence.

NEW COMPANIES.

WITT AND WESTLEY, LTD.—This private company was registered on December 10, with a capital of £2,500 in £1 shares (1,000 10 per cent. cumulative pref.). Objects: To take over the business carried on by A. E. Westley, as "Witt and Westley," and to carry on the business of manufacturers of and dealers in photographic mounts, albums, frames, materials and stationery, cardboard articles, etc. The subscribers (each with one ordinary share) are: A. E. Westley, Osda House, 13, Bishops Court, Old Bailey, E.C.4, mount manufacturers' agent; A. V. Finch, 13, Oliver Road, Walthamstow, Essex, solicitor's clerk. The first directors are: A. E. Westley and three others to be appointed by the subscribers. Registered office: Osda House, 13, Bishops Court, Old Bailey, E.C.4.

News and Notes.

ONE PHOTOGRAPH IN 100 YEARS.—Miss Mary Robson, of Woodbine Terrace, Gateshead, who has just celebrated her 100th birthday, declares she has only once been photographed.

A BARNET SHOWCARD.—Messrs. Elliott & Sons send us one of their latest calendar showcards, produced in the striking style which characterises the work of their artist, Grimmond. Dealers should see that they obtain this most effective advertisement of Barnet plates and papers.

LANTERN SLIDES IN MURDER TRIAL.—During the closing stage of the sensational Kleppelsdorf Castle crime trial last Saturday in Berlin, the court was darkened to allow of the exhibition of photographic lantern slides made by a firearms expert (Herr Walter) to show wounds on the two murdered women.

ENSIGN FILM COMPETITION.—The first prize of £50 in this competition, which closed on October 31 last, has been awarded to Mr. P. Smith; the second prizes of £25 and £10 going to Dr. Walter J. McFeat and Mr. A. V. Loyns. In addition, Messrs. Houghtons, Ltd., have awarded 15 consolation prizes.

STOLEN ALDIS LENS.—An Aldis anastigmat enlarging lens, No. 105,288, of f/4.5 aperture and 6¾ inches focal length, has been stolen from the dark-room of the Birmingham Photographic Society. Any dealer to whom the lens may be offered is asked to communicate with the hon. secretary at Birmingham Medical Institute Buildings, Edmund Street, Birmingham.

PHOTOGRAPHY ON THE STAGE.—Photography is made to play an amusing part in the show now being run by the Co-optimists at the Palace Theatre. During the performance a photographer comes on to take a flashlight picture of the company. The lights are lowered, and after the usual blinding flash, the company is discovered with blackened faces, shaking tambourines and bones with gusto.

PHOTOGRAPHS THAT WOULD ENSURE PEACE.—Mr. D. W. Griffith, the famous film producer, says that if the United States Government will lend him the battleships it is proposed to "scrap," he would create such a picture as would make anyone afraid to start another war. To the Secretary of the Navy he writes: "We believe that the motion picture is more powerful than any other medium of expression; that this fleet serving dramatically in the films could bring to the world a message of peace as vigorous and convincing as it has always brought the story of war."

PORTRAITS BY MR. WALTER STONEMAN.—The forthcoming exhibition of camera portraits, entitled "Men of Mark," by Mr. Walter Stoneman, F.R.P.S., should be of special interest in view of the fact that Mr. Stoneman is now sole governing director of Messrs. J. Russell & Sons, the well-known photographers of Baker Street, who have now for seventy years been in close touch with the Royal and official life of the nation. With three or four exceptions, the photographs selected have been taken in the studio in the ordinary course of his profession during the last four or five years, and represent a straightforward attempt to convey through the camera a real likeness and true craftmanship.

SCOTTISH NATIONAL SALON.—The entry form for the fourteenth Scottish National Salon has now been published and may be obtained on application to the secretary, Mr. James F. Smellie, Braefindon, Allanshaw Street, Hamilton. The Salon will be held at Hamilton from February 11 to 25. Entries must be received on or before January 23 and pictures not later than January 31. Entry forms should be addressed to Mr. Smellie at the above address and the pictures themselves to the Parish Halls, Chapel Street, Hamilton. As in previous years, the Salon is open to the work of photographers resident in Scotland and to that of Scots residing in other countries. Pictures may be sent framed, unframed or in passe-partout mounting. The selection committee consists of Messrs. Arch. Cochrane, Robert Chalmers and J. Campbell Harper.

PHOTOGRAPHY AT MOUNT EVEREST.—A "Times" special correspondent has been having a talk with Colonel Howard Bury, of the Mount Everest Expedition. Colonel Bury, speaking of the natives, was asked what impressed them. "Photographs," he replied. "These and a camera they had never seen before. They took a huge delight in being photographed, and nothing pleased them more than being given a copy of the picture. There was an old man, a very old man, in fact, the head abbot of a monastery at Shekar Tchöde. He was a reincarnation—these people all believe in reincarnation—and we took a photograph of him. A hundred miles from the monastery we were asked for copies of that portrait. No present was so acceptable, for the people worshipped the abbot as a holy man, and the photographs of him we gave them they put in their shrines."

THE WELLINGTON £1,000 COMPETITION.—Messrs. Wellington and Ward announce the following awards of the prizes, amounting in all to £1,000, offered by them to professional photographers for the most beautiful portraits of women: 1st prize (£300), Mr. Angus Basil, 100, Tottenham Court Road, London, W.; 2nd prize (£200), Mr. Lionel Wood, 32, Preston Street, Brighton; 3rd prize (£150), Messrs. Foulsham & Banfield, 49, Old Bond Street, London, W.1. The judges were the Earl of Carnarvon, Lady Diana Duff-Cooper and Mr. Alfred Ellis. In addition to the prizes awarded to the photographers, the sitters receive respectively £200, £100 and £50. This is the first occasion on which a competition has been organised on these lines, and Messrs. Wellington and Ward report that the large entries demonstrate the very great impetus to the purchase of studio portraits on the part of the public which it has provided.

GEOLOGICAL PHOTOGRAPHS.—The British Association has issued the twentieth report of its Committee on Photographs of Geological Interest. Professor S. H. Reynolds, of the University of Bristol, as secretary of the Committee, is glad to receive unmounted copies of any photographs recording noteworthy sections or exposures, or illustrating the relations of geological structure to scenery in the British Isles, and the prints so sent are registered and preserved for reference at the Museum of Practical Geology, 28, Jermyn Street, London. The inquirer who desires a copy for his own use is referred to the author of the photograph. The list attached to the twentieth report includes a large series of half-plate and quarter-plate pictures from Gloucestershire by Professor Reynolds, mainly illustrating the famous carboniferous sequence in the Avon gorge, and forty-five half-plate views of glacial deposits in Suffolk by that keen worker, the late W. Jerome Harrison. Mr. J. Ritchie contributes a series illustrating the erosion due to a cloud-burst in Aberdeenshire in 1891. It is much to be desired that funds would allow of the issue with such lists of small photo-

graphic reproductions from the registered views; but this would, of course, be impossible at the present time. Geologists near London, at any rate, have the advantage of consulting a very valuable series of records in an institution which has always been a bureau of scientific information.—"Nature."

MAKING FABRICS FIREPROOF.—One of the most satisfactory methods for reducing the risks of fire in the home is to ensure that all curtains and other draperies are fireproof. The following method enables this to be done quite easily and cheaply. In one quart of boiling water should be dissolved two ounces of borax, one ounce of common table salt, and five ounces of sal ammoniac (the same harmless substance as is used for electric batteries). The fabrics which are to be fireproofed should be soaked in this solution for about a quarter of an hour, when they may be gently squeezed and hung up to dry. In most cases this fireproofing process does not affect coloured fabrics, but it is advisable to first "try-out" a small portion of the fabric. Where fabrics require stiffening a suitable amount of starch may be added to the fireproofing solution. Fabrics treated in this manner cannot be ignited by flying sparks and are almost non-inflammable.—"Textile Chemist."

HACKNEY SOCIETY'S PHOTOGRAPHS AT R.P.S.—At the request of the President and Council of the Royal Photographic Society a House Exhibition by members of the Hackney Society has been arranged at 35, Russell Square. The work which has won distinction in the strong annual exhibitions of this old-established North London Society has naturally been largely drawn upon, but there is a considerable leaven of new work also. The prints, which have been carefully selected, mounted and hung make a very favourable impression. Most have been made by the bromide process, the most popular in the Hackney Society, as in many others. Individual aims are, however, sufficiently varied to overcome any tendency to sameness. Bromoil work has been largely omitted on account of the danger of injury where prints are shown unglazed, as is the case in this exhibition. The collection is particularly strong in landscape and kindred subjects. Two of the leading workers of the Society, Messrs. Selfe and Capper, are very successful in their renderings of fine atmospheric effects. Mr. S. W. Shore shows some striking portraits, and the quality of Mr. R. H. Heath's architectural work comes near to perfection. There are some interesting, if small, photographs of birds by Mr. O. G. Pike. Mr. H. E. Wood's London subjects are numerous and well treated. Other members, whose prints are sure to attract attention, are Messrs. J. Caudle, W. H. Clark, J. Grice, H. Lamplough, A. J. Linford, and R. Mason. It must not be inferred from these remarks that the work of others is unworthy of notice, for the general level is high, and almost every branch of photography has skilled exponents in the Hackney Society. Members of societies and others will find the Exhibition, which will be open free on week-days from 11 a.m. to 5 p.m. till January 7, well worth a visit.

INVENTIONS IN COLOUR PHOTOGRAPHY.

To the Editors.

Gentlemen,—My attention has been called to a letter from Mr. F. E. Ives, which appeared in your issue of December 2, in which he claims priority for type of a single exposure tricolour camera, of which one was the subject of a patent granted me in 1897.

I should say that I never heard of a camera of this type being patented by Mr. Ives, and think perhaps he refers to his invention of the Kromskop, an instrument which showed beautiful results in viewing three-coloured projected images superimposed on one plane.

If it is the Kromskop he has in mind surely he would not contend that was an exposure camera. It was a viewing instrument entirely, and neither designed for nor capable of taking tricolour negatives. Its essentials were solely and purely for the function of a viewing instrument and nothing else.

Honour and credit are due to Mr. Ives for his invention of the Kromskop; it marked a great advance in showing photographic results in natural colours, which were a pleasure to look at, but if in its construction he has utilised a well-known principle of a natural law, that coloured media will absorb rays of a complementary colour, that principle had still to be worked on and applied in the design and construction of a photographic taking camera, and I have never heard, nor can I trace, that Ives had a camera of the same type as the one I patented in 1897.

Shortly after (20 days) Mr. Ives had made application for patent for the Kromskop, he made application for a taking camera, Patent No. 3,784, 1895 (British Patent). He uses two transparent mirrors of plain glass, having plain surfaces placed at an angle with each other, to form a reflector wedge shaped to avoid double images.

The same camera is provided with four additional mirrors, which are opaque, and three object lenses, obviously an altogether different type of camera.

This much I am indebted to Mr. Ives: it was the charm of his results in the Kromskop that caused me first to turn my attention to the invention of a camera that should enable me to produce the necessary positives for viewing. Having purchased a Kromskop I endeavoured to buy a taking camera, but neither the Kromskop Company nor anyone else could supply me.

The elements of the "Kromograms" at that time were printed viewing positives, I was informed by the representatives of the company, from negatives obtained by successive exposures through suitable screens.

Having made a practicable instrument otherwise unobtainable, I applied for and was granted a patent in 1897. That was about a year after I had been having the camera in experimental use. I subsequently found that practically simultaneously White had been granted a patent for a camera on similar lines to those I employed. Apart from this I can find no trace of any of the same type, nor anyone having for the purpose of taking tricolour negatives simultaneously used the principle of which advantage is also taken in the Kromskop.

I have also read Mr. Hamburger's letter appearing in to-day's issue of the "Journal," in which he states that until its advent [the Polychromide Camera, Patent No. 28,722, 1912] "negatives in perfect register were not obtainable."

On February 16, 1906, some one else made a similar claim for his invention, and was equally sweeping in his endeavour to prove a negative. In correspondence in the "B.J." at that time I submitted negatives in proof of my assertion that I could produce sets of negatives from my single exposure tricolour camera identical in size and focus. In the "Journal" of March 9, 1906, you were pleased to state that the negatives submitted established the claim.

For upwards of eighteen years cameras have been made to my specifications producing negatives correct in register, focus and colour separation.—I am, yours faithfully,

EDWIN T. BUTLER.

26, Craven Park, N.W.10, December 9.

TANK DEVELOPMENT.

To the Editors.

Gentlemen,—With regard to your recent correspondence on the subject of tank development, as manufacturers specialising in the production of these tanks, both of teak and enamel, on a large scale for the photographic and cinema professions, we are interested in the matter. We have heard many discussions in favour of tank development, whether it be for plates, flat or roll films, and is our opinion, and we think it is very generally held, there is no need whatever to create movement in the developer, as the necessary stir is caused by the taking out and placing in of the different batches.

From our experience of the past twelve months we are of opinion that tank development is on the increase, especially for roll films, and we also find that the tanks made completely of teak are greatly in favour.—Faithfully yours,

For and on behalf of F. Brodrick, Ltd.,
C. BRABANT SMITH,
Director.

Answers to Correspondents.

In accordance with our present practice a relatively small space is allotted in each issue to replies to correspondents.

We will answer by post if stamped and addressed envelope is enclosed for reply; 5-cent International Coupon, from readers abroad.

Queries to be answered in the Friday's "Journal" must reach us not later than Tuesday (posted Monday), and should be addressed to the Editors.

F. A.—The only lamp of sufficient power, apart from electric current or gas, is the Blanchard oil incandescent lamp, made by Blanchard Lamps, Ltd., 151, Farringdon Road, London, E.C.1.

J. J.—For removing the film the most effective means is to dip the negative in a very hot solution of caustic potash or caustic soda. A second or two in this bath will remove the film from most negatives, whether hardened or not, or at any rate will soften it so much that it can be quickly scrubbed off with a hard brush.

S. F.—It is quite an easy matter to make lantern slides. You cannot do better than write to the Ilford Company, Ilford, London, E., for a free booklet entitled "Lantern Slides on Dry Plates," which they issue. The Wratten Division of Messrs. Kodak, Ltd., have also a free booklet giving instructions in the use of the Wratten lantern plates.

C. M.—For taking carte-de-visites in a studio of 22 ft. run you cannot afford to have a longer focus than 7 ins., that is allowing 5 ft. for the space required behind camera and behind sitter. With this lens, of course, you can take cabinets and other larger pictures. For covering a half-plate the lens would have to be a pretty good anastigmat. We suggest that you select one of about f/6 maximum aperture.

A. H.—(1) As a very rough approximation, owing to the differences between plates and the different degrees of density to which they are developed, suppose we say from 12 to 20 plates in 66 ozs. of 1 : 100 developing solution. Your tank full of developer is equivalent to a little over ½ oz. of the stock solution, which will not develop a great number of plates, however long you allow it to act. (2) The Brunswick black will not affect the developer, but it comes off after a while, probably owing to the action of the alkali in the developer.

C. R. O.—(1) Conditions are very much the same as regards cheap work as here. (2) So far as we know there are no restrictions as regards photography on board ship. (3) Sea-water can be used without ill-effects for washing plates and prints. The Ilford Co. published a result of tests on this point many years ago. (4) Amidol is one of the best developers, especially when a fairly large quantity of sulphate of soda (Glauber salts) is used in it. But the best recommendation we can make as regards developing in tropical climates is to use the Tropical hardener, worked out by the Ilford Co. a year or two ago, and sold by Johnsons, 23, Cross Street, Finsbury, E.C.

J. T.—The true-to-scale process consists in first making a blue print which, without having washed it or treating it in any way after removal from the printing frame, is laid down upon a jelly prepared with gelatine and a certain proportion of ferrous ammonium sulphate. We cannot give a formula for the latter, as the amount of ferrous ammonium sulphate varies with different qualities of gelatine. After contact for a while the blue print is removed, and then the impression which it leaves may be inked up with a greasy ink applied with a roller and impressions taken off. Under good working conditions as many as fifty satisfactory proofs can be pulled.

A. W.—The usual practice with sitters of the character you describe is to knife away as much of the surplus flesh as may be necessary. It is not uncommon to practically make a new outline in this way to both face and figure. Your best plan would be to send one of your negatives to a good retoucher, say, Mr. T. S. Bruce, 4, Villas-on-Heath, Vale, Hampstead, London, N.W.3, and ask him to make your sitter as refined as possible. Print a proof first and then you will be able to note the change. As far as lighting goes, we should be inclined to throw one side of the face into rather deep shadow. It is a good plan to take the heads of such sitters rather smaller than usual.

A. L.—We see no reason why you should not do good work with acetylene lighting, as the light is very white and actinic, but so far as we know, there is no special fitting made for using it for portrait work. Messrs. Thorn and Hoddle, 151, Victoria Street, Westminster, London, S.W.1, would make you one to order: they have fitted up several studios. We should think about 20 burners would be required. You cannot do better than to communicate your wants to Mr. D. Charles, 45, Beaufort Road, Kingston-on-Thames, who makes a very efficient flash lamp, and would doubtless make a fireproof bag for it. We do not recommend flashlight for ordinary studio work, although it is invaluable for restless children and home portraiture.

W. B.—(1) The address of the Premier Optical Co. is 63, Bolton Road, Stratford, London, E.15. (2) It is very doubtful if the lens would be improved by repolishing. Before having this done, we think it would be worth while to have all the interior of the lens thoroughly dead-blacked, say with "Nigrogene" made by the Vanguard Co., Maidenhead, as the inside is far from being dead black at the present time to an extent which with a lens of large glasses like this would have some effect in causing flatness. It is possible that the front and rear elements are not in absolutely correct position. The front element has a very peculiar kind of fitting, and the rear element looks as though it had had a fall, sufficient to upset the centering and to account perhaps for some veiled definition.

G. N.—For fairly close-up exposures of football play and other sports' subjects a speed of about 1-250th of a second is about the average. This probably means that you want to use a focal plane shutter at a speed marking of about 1-500th or 1-600th. In our opinion you had best use either an ordinary folding-focal plane, or a box reflex, such as the "Soho." For fast work, especially if you have a reflex, the lens aperture should be *f*/4.5, but with an ordinary folding focal plane, especially with close-up subjects, it is very difficult to be certain of focus when using this aperture, and we daresay many pressmen work with the lens at *f*/6, or even *f*/8, whenever the light allows them a reasonable chance. For the studio lighting we suggest about 4,000 c.p., distributed among four half-watt lamps, each of 1,000 c.p.

J. N.—For colouring with oil colours, which are those usually employed by professional slide colourists, you cannot do better than have the best tube oil colours of Winsor and Newton, or Rowney, from any artists' dealer. For colouring with dyes, you can obtain a very convenient set of tints from Johnson & Sons, 23, Cross Street, Finsbury, London, E.C.2, or the Vanguard Co., Maidenhead. (1) It is best to avoid all use of alum if prints are to be coloured with dyes, but we do not think it matters as regards using oil colours. (2) The dyes are quite effective in use, though not of the same degree of permanence as the oil colours. (3) No special preparation of the gelatine film is necessary. You should get the little book, "Colouring Photographs and Lantern Slides," by R. Penlake, published by Iliffe & Sons, 20, Tudor Street, London, E.C.4.

THE BRITISH

JOURNAL OF PHOTOGRAPHY.

No. 3217. Vol. LXVIII. FRIDAY, DECEMBER 30, 1921. Price Fourpence.

Contents.

SUMMARY

The index to the sixty-eighth annual volume of the "British Journal" and to the fifteenth volume of the "Colour Photography" Supplement is published with this issue.

We give a new formula for the hypo-alum toning bath worked out by the Kodak Company, and recently embodied in the instructions for Kodak bromide paper. The new feature is the method of ripening, which is done by incorporating a definite quantity of silver iodide with the hypo and alum. (P. 773.)

Dr. Marcus G. Lovelace, in a paper in the "American Annual of Photography," gives very practical instruction in the oil colouring of lantern-slides, particularly in the production of an even tint of colour by fingering. (P. 776.)

In a contributed article Mr. A. H. Hall describes experiments on the range of tones obtained on gaslight paper by the method of bleaching, partly re-developing and following with the sulphide bath. (P. 775.)

The report of the Croydon Camera Club emphasises certain important points in the Carbro process, recently demonstrated there by Mr. Braham, and proceeds to some speculations regarding methods of producing diffused definition in enlargements. (P. 783.)

In a leading article on the equipment of a small studio for the beginner in professional portrait photography we refer to the choice of lenses and camera and to the fitting of the dark-room. (P. 774.)

In the case of many sitters the advantage of using a panchromatic plate for portraits which are to be coloured is very considerable. (P. 773.)

In making full-length portraits by flashlight, as frequently is done of sitters in fancy dress at this time of year, the proper use of a diffusing screen will greatly help in obtaining even illumination. (P. 774.)

A delicate case respecting ownership of copyright in photographs of similar subjects is the subject of an answer to a correspondent. (P. 784.)

We publish this week the comprehensive list of publications relating to the origins of aerial photography appended by M. L. P. Clerc to his recent Traill Taylor lecture on this subject. This compilation provides a key to the successive steps taken in many directions as a result of the wide employment of aerial cameras very soon after the outbreak of war. (P. 778.)

The first volume of "Photographic Abstracts" has been completed by the Scientific and Technical Group of the Royal Photographic Society. A notice of this work and of others on optical projection and pictorial photography appears under "New Books." (P. 782.)

Particulars of a method of stereo-cinematographic projection are contained in a recent patent specification. (P. 780.)

EX CATHEDRA.

Portraits for Colouring. Even those who are most prejudiced against the use of panchromatic plates for ordinary portrait work must acknowledge their valne when the object is to produce a hand-coloured portrait. A sitter with blue eyes and bright golden hair is an ideal subject for colouring, and at the same time one which it is almost impossible to render decently without faking during printing. If the hair is shaded with matt varnish or colour on the back of the negative the scale of tones, bad as it is already, is further falsified by the hand-work. If, however, a panchromatic plate, with a fairly light filter, which need not require more than double the exposure, be used, a print giving a close approximation to the visual value of the colouring will be obtained without trouble. Even without the filter a great improvement will be manifest, but the use of the filter is to be recommended. A rather soft-working paper should be chosen to avoid heavy shadows, and liver of sulphur or hypo alum toning should be adopted, as these do not block up the shadows of a strong print or give a foxy colour to a delicate one. Carbon is the ideal process for colouring, though many less skilled colourists avoid it, as the surface does not take the tints as freely as a bromide or P.O.P. does.

* * *

Hypo-Alum Toning. The progress which has been made of late in the manufacture of development papers exhibiting more widely marked characteristics, is perhaps one of the causes of the varying experience in the use of the hypo-alum toning bath. As is well known, the manner of "ripening" the bath by introducing into it a certain quantity of silver compound has a good deal to do with its proper toning action, and is found variously to influence, according to the nature of the paper on which the prints are made, the particular tone which is obtained. The method of ripening a bath by addition of clippings of waste P.O.P. or bromide paper is certainly a plan which is preferable to the addition of silver nitrate, sometimes recommended. But a still better system, so it seems to us, from the point of view of standardising the hypo-alum toning process is that which has just been embodied by the Kodak Company in the instructions for toning Kodak bromide paper by the hypo-alum method. Probably many who have had difficulty in the process will be interested in making trial of this new bath the instructions for making which are as follows:—Dissolve 1 lb. (400 gms.) of hypo in 80 ozs. (2 litres) of hot water, then add 3½ ozs. (90 gms.) of ordinary alum; stir well and boil for two or three minutes; cool down to about 150 deg. F. (65 deg. C.) and add the following silver ripener:—Dissolve 20 grs. (1 gm.) of silver nitrate in 1 oz. (30 c.c.s.) of water and add, drop by drop, .880 ammonia until the precipitate first formed is just re-dissolved; (stir vigorously while adding the ammonia). Add this to the hypo-alum mixture and stir well. In a further ounce (30 c.c.s.) of water

dissolve 40 grs. (3 gms.) of potassium iodide; add this to the hypo-alum mixture and stir well. This bath can be used over and over again. It may be kept up to its original bulk by the occasional addition of fresh solution, and when it ceases to tone satisfactorily it should be thrown away. Prints for toning by this method should be fixed as usual, briefly rinsed in water, soaked for ten minutes in a saturated solution of alum, rinsed, and then toned at a temperature of 140 deg. F. (60 deg. C.). After toning, sponge the prints with lukewarm water to remove sediment, and wash as usual.

* * *

The Annual Index. With this issue is presented the index to the sixty-eighth annual volume of the "British Journal," together with that of the fifteenth volume of the "Colour Photography" Supplement. The work of preparing this A.B.C. pointer to the contents of the two publications is perhaps greater than many people imagine. Indexing, unfortunately, is one of those arts, the practitioners of which obtain plenty of criticism for any faults which their work may exhibit, but little credit for the care and labour which they expend in making a large miscellany of information quickly accessible to those who are studying a subject or seeking a particular item. We think we can say, on behalf of our indexers, that no subject matter, which is likely to be of permanent interest, escapes inclusion in their compilation. It may be worth while to point out that an indexer naturally does not assume familiarity with the volume on the part of those who will use his index, and, therefore, drafts his entries in accordance with the actual subject-matter, largely disregarding titles given to articles or paragraphs if these are non-descriptive. On no other plan would it be possible to compile an index of general usefulness both to immediate users and to those who may refer to the volumes in years to come.

* * *

Fancy Dress Portraits. At the present season, when there are many orders for fancy dress portraits which are usually taken as full lengths, a hint or two on overcoming one of the most serious difficulties attendant upon this class of work may be useful to some of our readers. The difficulty we have in mind is that of securing adequate illumination of the lower part of the figure, which arises from the fact that the source of light is so much farther from the sitter's feet than from his head. With the light at a height of 8 feet it may be assumed that it is only 4 feet from the head of the subject, while it will be nearly 9 feet from his boots, which will therefore receive less than a quarter of the light compared with that which falls upon the face. In the case of a single lamp the remedy is to use a diffusing screen covered with stout muslin to shade the upper part of the figure only, and to give just enough exposure to render the lower part properly. Here the despised head-rest, better used as a back-rest, will serve to keep the sitter steady. If several half-watt lamps are used, one or two may be lowered to 4 or 5 feet from the floor, and a diffuser placed so as to prevent the shadows in the face from being destroyed, that is to say, to intercept any upward rays.

* * *

Flashlight Apparatus. The occasional worker with flashlight is rarely properly equipped for his job, and therefore usually approaches it with some degree of trepidation. Many of the lamps designed for use with explosive powders have the mechanism exposed to the flame, with the result that they become corroded and unreliable, the springs losing their resiliency and failing to ignite the match or cap. It is a wise precaution to clean all moving parts as soon as possible after use and to wrap the lamp in waxed paper before putting it away, thus saving valuable time when the call comes. In case of failure it is advisable to be provided with an alternate means of ignition, and there is none better than a tuft of guncotton, which can be embedded in the powder and touched off with a lighted taper fixed at the end of a long rod or walking-stick. Touch-paper is quite effective if bone dry, but as it takes several seconds for the sparks to reach the powder, there is a risk of the group being spoiled by some of the members watching the lamp. Guncotton or pyroxyline can be obtained from such firms as Johnsons or Hopkin & Williams. For safety's sake each tuft, about the size of a nutmeg, should be carried in a separate corked vial or short test tube. Tin boxes should be eschewed, as there is the possibility of a spark being struck when opening or closing.

EQUIPMENT OF A SMALL STUDIO.

II.

It is to be presumed that a small studio must be equipped with due regard to economy both of money and space, so that large and costly apparatus is not desirable. In few modern businesses are direct portraits larger than whole-plate size sent out, and therefore a studio camera with lenses suitable for that size should be chosen. It should be fitted with central swings, horizontal and vertical, and preferably have a repeating back, although this latter is not essential. In fact, if the camera has to be used occasionally out of doors it is better to sacrifice this fitment and select an ordinary parallel bellows field camera, which will answer as well as a special studio camera for portrait work and yet be quite portable. It is possible to fit such a camera with a removable repeating back, but as a rule the framework is hardly heavy enough to make this safe, so that it is better to be satisfied with the ordinary slides.

If much outdoor work is anticipated a separate camera should be provided, and should be for 12 x 10 plates, as this size is most useful for wedding and football groups, architectural or engineering subjects, and commercial work generally. It may be argued that enlargements could be supplied from whole-plate negatives, and that is true of some subjects, but for groups in which a number of faces require retouching, and for machinery which has often to be blocked out, full-sized negatives are most satisfactory.

It should be kept in mind, when selecting lenses, to choose such as will serve for more than one size of plate. For example, an anastigmat of 8 inches focal length will answer for rapid outdoor work on a half-plate, for cabinet full lengths in a very short studio, and will give a sufficiently wide angle for most purposes upon a 12 x 10. Bearing this in mind, a useful outfit to work both in-doors and out would be a 16- or 17-inch anastigmat for large groups and general work, on 12 x 10 outdoors and for cabinet and whole-plate work in the studio; the aforesaid 8-inch anastigmat, both with an aperture of $f/5.6$ to $f/6.3$; and a very rapid portrait lens of $10\frac{1}{2}$ or 11 inches focus for children and other quick work in the studio only. Other lenses may be added as opportunity offers, but a good start may be made with these three.

The studio camera stand should be of the Semi-Centennial or Hana type, in preference to the ordinary three- or four-legged patterns. Few of the latter will go near enough to the floor for children's portraits, and as a rule are not so steady. For outdoor work the tripod should be of generous size, a 10- or 12-inch head not being too large. The legs should have a good range of sliding movement, as a low stand is often wanted.

Every effort should be made, in fitting up the dark-room, to utilise every inch of space to the best advantage.

It is impossible to indicate how this may be done, as the dimensions and shape of the room will have to be considered. As a general instruction we suggest that as much space as possible should be devoted to sinks, which can easily be covered when a dry bench is required. It should always be possible for plates or prints to be washing while development or printing is being carried on, and this cannot be done conveniently in a small sink. It may be possible to work with one small sink, but it means many wasted hours in the course of a week, a consideration to the single-handed worker. Cupboards for exposed and unexposed plates should be fixed at a convenient height over the filling-in bench, and hooks provided for hanging spare inner carriers. Under the sink a rack for dishes and a waste box or tub should find places; an empty hypo cask will answer for the latter. An efficient printing box is a *sine quâ non* in any up-to-date dark-room, and, although electric light is the most convenient, gas, or even oil, may be used as the illuminant. If these are used it is necessary to work by reflected light, a mirror or even a white card serving to deflect the rays. If constructing a home-made box, the movable yellow shutter should be made as small as possible and close up to the light. If so arranged and properly balanced, no more effort will be required to make the exposure than is exerted upon an electric switch. In the workroom a strong bench should be constructed to carry the dry-mounting press, and this should not be too high. In most cases the press is fixed too high to be worked without an effort. The trimmer may find a place on the same bench, but only if there be a good light, which is also necessary for the "tacking on" process.

The retouching desk will probably have to be placed in the workroom. It should be of adequate size, not less than 20 inches square; the cover should be smooth and arranged so that it can be shut down to form a slope for spotting and colouring.

An almost indispensable item in even the smallest business is a good enlarging lantern, as it allows of prints of any size being made without delay. The half-plate size, with 8½-inch condenser, is the most generally useful, and a small half-watt lamp of, say, 250 c.p., the most convenient illuminant, failing which, an incandescent gas burner or acetylene can be used. Oil lamps are troublesome and odorous, and not to be recommended; if acetylene be objected to, the spirit incandescent lamp will be found most satisfactory. The enlarger should be fixed in a position in which it is always ready for use. In a small dark-room this may be done by means of a strong bracket for the lantern well above the sink, the easel being suspended from a wooden gantry upon which it can be moved to and fro.

VARIOUS WARM TONES OF GASLIGHT PAPER.

It is not always easy to get good tones on gaslight paper by sulphide toning, and the writer recently carried out certain experiments to see what range of tones he could obtain between the cold black of a normally-developed print down to a sepia with rather less yellow than is generally found in a print toned in the usual method by bleaching and darkening in sodium sulphide.

A test was made by the method advocated by Messrs. Kodak for Kodura paper, by bleaching in the usual ferricyanide bath with potassium bromide, partial re-development in a dilute developer, with subsequent immersion in sodium sulphide.

A negative was chosen and prints made on Novex gaslight paper, this paper being selected as development is rather slower than with most brands, and consequently the deposit forming the image might be expected to be in a specially suitable condition for toning.

The exposure was such that a good print was obtained in 30 seconds with D 50 developer, standard formula, at 62 deg. F.

The whole of the prints were exposed under identical conditions but developed for 90 seconds each to make some allowance for any apparent loss in depth due to the subsequent colour.

The prints in the set were practically indistinguishable from each other.

The prints were then bleached singly, washed in running water for 90 seconds, and immersed for various times in Wellington metol-hydroquinone borax developer of 10 per cent. normal strength.

The standard formula is as follows:—

Metol	1 gm.
Hydroquinone	2.5 gms.
Sodium sulphite (cryst.)	10 gms.
Borax	10 gms.
Water	500 c.c.s.

This developer was chosen as being slow working without the addition of bromide.

The whole of the operations were conducted by the electric light of a 60-watt half-watt lamp.

The following operations consisted in rinsing the print for 30 seconds in running water, and sulphiding in a bath of sodium sulphide of normal strength. Each print was developed in a separate portion of the dilute developer.

The attached table gives the results and also some alternative methods of obtaining the warmer sepia tones. Plain bleaching and sulphiding was not attempted as the results are too yellow to please the writer.

Print No.	Time in Developer	Colour on Removal from Developer.	Resulting Colour of Finished Print.	Remarks.
1	—	—	Black.	Normal print.
2	Till blackened	—	Warm Black.	Full strength developer used and no sulphiding.
3	30 mins.	Chocolate Red with tinge of Violet.	Warm Black—Brown Black.	
4	20 mins.	Chocolate Red	Cool Sepia.	The most useful range.
5	15 mins.	Red	Messotint Sepia.	
6	12 mins.	Lighter Red.	Sepia.	
7	9 mins.	Pale Red	Warm Sepia	
8	6 mins.	Very Pale Red	Warm Sepia, with distinct tinge of Yellow	

ALTERNATIVE TESTS.

Print No.	First bath.	Second bath.	Third bath.	Fourth bath.	Remarks.
9	Presulphide for 5 mins.	Bleach	Sulphide	—	Intermediate between 10 and 11
10	Bleach	10 secs. in carbonate of soda	Sulphide	—	Most yellow
11	Presulphide for 5 mins.	Bleach	10 secs. in carbonate of soda	Sulphide	Least yellow

NOTE.—9, 10 and 11 all lie between 6 and 7 in Colour, and exhibit rather more red and less yellow.

The writer was more interested in getting practical results which appeared to be capable of being repeated than in the scientific side of the experiment, and consequently omitted print No. 6 from the first series. This print was made subsequently, and dried, and was, the next evening, bleached and treated in the developer for a period half-way between the times given for prints No. 5 and 7. The resulting tone would enable anyone to place the print in its correct sequence in the set, which appears to be a striking commentary on the reliability of the method.

Print Nos. 9, 10 and 11 do not show any striking differences, but the colours are all pleasing, No. 11 being perhaps the best, and No. 10 showing more yellow than the other two. The use of carbonate of soda was suggested by the experiments recorded in the "British Journal" for July 29, 1921, by Mr. E. R. Bullock.

I will leave the editor to comment on the tones, but prints 2—7 bear a close resemblance to carbons of the colours described in the table. A. H. Hall.

[Of the series of prints which Mr. Hall very kindly sends for our inspection Nos. 2 and 3 represent the importation of just a trace of warmth into the black of the original print. No. 4 has distinct warmth of tone; No. 5 a little more. The remaining prints, Nos. 6 to 11, do not exhibit very appreciable difference as regards colour. All of them would, perhaps, be described as a pleasing sepia brown. Without exception the scale of tones in the original print is excellently retained. Eds., "B.J."]

COLOURING LANTERN SLIDES.

[In the 1922 volume of the "American Annual of Photography," just issued by Messrs. George Murphy, of New York, is the following exceedingly practical article on the colouring of lantern-slides. Dr. Lovelace does not attempt to teach the æstheties of this branch of work—and very wisely so, since that is entirely a question of individual taste and aptitude—but he deals in the clearest way with the technique of the oil colouring of slides. In view of the commercial opportunities which frequently occur for the supply of coloured slides, we give his very practical directions a place in our pages.—Eds. "B.J."]

Lantern slides, to my mind, are one of the most beautiful forms of the photographic image, and when properly coloured are even superior to the plain slide. I have heard many people express preference for the hand-coloured slide to the Autochrome or Paget, although the writer cannot agree with them on this point, for to my mind there is no form of photograph that will compare with a good colour plate.

Many miles of direction have been written about the colouring of lantern slides, but, with one exception, I have never seen any that were really practical. Most people use water colours. While it is possible to use them so that they do not look like the terrible things we see in the theatres announcing "The Perils of Pekin in 5 reels, with George Manleigh and Lovine Sweet," it is not often that they are anything but a warning to young slide painters.

Nothing is more pleasing to the beginner than to get his colour eight shades too dark, using some of the various aniline colours, and then try to get the colour out. It can be done—sometimes. Usually your slide is spoiled. With the use of oil colours all these troubles are avoided, and there is really only one difficulty to contend with—what this is I will explain at length.

For materials I am going to give specific names, as I have found that all brands of paint do not work the same, and some will not work at all. Get enough colours—life is too short to spend time mixing shades all the time. The outfit that I am giving here will only cost three or four dollars at the most, and will paint upward of a million slides—easily.

The colours I use are "Winsor and Newton Transparent Oil Colours"—a special colour made for transparent work. Get the following colours:—Gamboge, Chinese Orange, Mars Yellow, Alizarin Crimson, Crimson Lake, New Blue, Prussian Blue, Brown Pink, Italian Pink, Burnt Sienna, Vandyke Brown. For medium to mix them with I must acknowledge my indebtedness to Mr. Alfred H. Saunders, for a formula given in the "Annual" some years ago, and which I reprint here. It is the best medium I know, and I have tried them all, or nearly all.

Transparent gold size	...	...	4 parts.
Pure linseed oil	...	...	2 parts.
Pure turpentine	...	...	1 part.

Get these from a dealer in artists' materials, or you will *not* get linseed oil or turpentine, but some villainous compound which will ruin your work. Mix these well, and you are ready.

Dust is the prime enemy of the slide painter—guard against it as a plague by whatever means is necessary. Do not paint by daylight—use a light of the same colour as the one by which it will be shown, or as near as possible. A half-watt bulb—a white one—is first rate: then use a piece of opal glass, not ground, but opal for an easel. Put it at an angle of about 45 degrees, and your easel is ready. For a palette nothing is better than another piece of glass, not opal, but clear, prepared as follows:—Arrange your colours in a row, all reds together, all blues together, etc.; then take a brush, and put a small dab of each colour (mixed with a little of the medium given above) on the top edge of the glass. After they are all on, make a list, and paste it on the back of your palette, so that it can be read from the front. By merely looking at the row of colours on the top edge of your palette, you will know what colour you want to put out and use. This may seem a small item, but, after painting slides awhile, it will be found very valuable as a time saver.

Brushes are a big item. If they are good you will have little trouble in doing good work, but if they are poor they are an endless nuisance, as a hair from a brush ruins a slide if left on, and usually you will spoil the slide if you try to remove the hair.

The brushes used are called flat top, camel's hair, china painters' shaders, round, in quills. That is the full name, and Devoe and Reynolds make an excellent grade. Get some handles for them when ordering. You will need about four—ranging from an eighth to a little more than a quarter of an inch in diameter. They are round stubby brushes like a short cylinder of hair, but when filled with colour they will fan out until they will draw a line as fine as a hair. *Do not try* to use the ordinary pointed water colour brush if you want success.

The most difficult thing to learn in slide painting is the operation called fingering. It is not possible to put large tints on a slide by means of a brush. Streaks will show in spite of all that can be done to prevent them. Large tints are put on in this way:—A small amount of colour is put on the palette and mixed with a little medium. It is then painted on the slide and then fingered. This is done by polishing the second finger of the right hand with a piece of pumice stone, under water, until the finger is smooth as glass, taking care not to rub until finger is raw. Dry the finger, and then finger as follows:—Start at the bottom of the tint

to be fingered, and dab with the ball of the finger that has been polished. Roll the finger as you do so, so that each dab is a short roll of the finger on the smooth part. Do not dab without rolling the finger: it's a waste of time. Do not drag the finger, the paint will smear. Dab lightly, do not press heavily. Roll the hand from the thumb side *toward* the little finger. Each dab must overlap the last one made, and the pressure must be even.

Much depends on the consistency of the paint. If the mixture of paint and medium is too thin—that is, there is too much medium—the mixture will remain in little mottled puddles after each finger dab. If the mixture is too stiff or too dry, you will have prints of the finger at each dab. When the paint and medium is working right, and is just dry enough, each dab will leave a little mark, and these will run together, and as fingering goes on will gradually form an even tint. Note the two conditions:—1st: If paint and medium mixture is too thin, it will leave little puddles of paint after it, like footprints on a wet floor. 2nd: If mixture is too thick, it will stick to finger, and leave imprints of the finger on the slide.

This may seem a little unnecessary attention to detail, but fingering a slide is one of the most important things, if not the *most* important of the whole process—without it it is hardly possible to paint any kind of a slide whatsoever.

If you do not succeed at first—and it's almost certain you won't—have some benzole handy, wash the colouring off, and you are ready to try it again.

Now for a slide—get a seascape, if possible—it's easiest—and proceed as follows:—Take a small quantity of Prussian Blue on the palette, and mix with a little medium. Take your slide and paint it all over with this colour. Lay your brush down and start to finger the colour even, watching for the faults I have just told you of. You may have to wash the slide off four or five times, but it will not be hurt if you are careful. Read the directions on fingering again. Finger from left to right along the bottom edge, wipe the finger clean, and start to finger the next section higher, being sure that the upper rows of dabs always overlap the one below it, and wiping finger clean at end of a row of dabs. You must learn to finger an even tint before you can do anything else, so have patience, and after a little, without any change in your method of working, you will find that you can put on a tint as smooth as can be. Remember what was said about the paint being too thin or too dry, keep trying, and soon it will be easy.

Suppose that you have had good luck the first time, and you have an even blue shade all over the slide. If it is too light you should have used a darker colour to start with—if it is too dark the original colour should have been lighter. If it is too dark, keep on fingering and wiping. If it is too light, dab on some more colour and finger again. When the colour is the right shade take a chamois stump (from a dealer in artists' materials) and wipe out all the places where you do *not* want blue—for instance, in a seascape—wipe out your beach, flecks of foam, boats, etc., leaving the blue over the sky and sea. Do *not* use cloth or anything but chamois, or you will have lint on the slide, which ruins it. Wipe the stump clean with benzole and a rag, and it will last a long time. Remember, if you spoil the slide in wiping out blue where it is not wanted, wash the whole slide with benzole and paint it again. Should you run over the edge, say, of a sail or a whitecap, and take some of the sky away, it can be fingered with a little care and blended so that it will not be necessary to paint the whole slide over.

After the blue is put on, and all detail where you will use other colours is wiped clean, put the slide into a tin box, say, about 8 × 10 × 2—made without solder, and with a tight-fitting lid. This is called the stove, and is for drying the paint hard. The slide must be heated to about 200 deg. for several hours in order to bake the paint dry and hard, which must be done between each painting. 200 to 250 deg. Fahrenheit for about three hours is enough: too *much* heat will cause paint to turn brown.

When slides are cool go ahead and paint in your detail as much as possible, taking care that wherever one colour goes over another the first one is baked before the other is put on. After you have painted your first slide, put it in the lantern and learn your mistakes. It will probably be too dense, too dark, have dust on it, hairs from the brush, etc., so do not be discouraged: just make it over again.

Many people like to blend a sky from a deep blue at the top to a fine red at the bottom—why, I don't know, but it is done, and this is the way it is done with oil colours. Start at the horizon with a sweep of Crimson lake, above that a strip of Prussian blue or New Blue, then above that a sweep of Vandyke brown.

Now start at the bottom and finger, blending them together, and the trick is done. Another combination of this sort is Italian pink, then Prussian blue, then Vandyke brown above that.

In painting waves, water, etc., coat entirely with blue, fingered on, and then put on light touches or coats of yellow and brown in order to make the green shades wanted. Grass is better made this way than by mixing colours. I would advise the slide painter to buy a few oil coloured slides; it will teach him more of what a well fingered sky and sea should look like than pages of description could ever do. In putting in clouds, they should be wiped clean of paint in this way. Take a small piece of chamois skin, and roll up into a small cylinder—wipe out the clouds with a circular motion and then finger smooth so that the sky blends into the clouds in order to avoid the "hole in the sky" effect that is all too common.

I am not going to attempt to tell you what colours to mix to make definite shades; it would take too long. The object of the glass palette with the sample colours on the top is to enable you to see what the colours look like when light shines through them, and with a little practice one can get shades that will fit any picture. An artist friend tells me that with the colours I have mentioned in the list a man could paint any picture that has ever been painted, so there you are.

Another word and I am done—oil colours are as permanent as can be made. Any water colours suitable for slides will (in time) bleach out when used in a powerful lantern. Why spend time to make them if they will bleach out in a short time? I am sure that anyone seeing a good oil slide will never use any more water colours, and I can assure you that if you will practise the above-given directions faithfully, you cannot help but succeed. I dislike giving rules exceedingly, but possibly these brief rules will help the young painter.

(1) Put in your largest tint or your blue first—that which must be fingered and then bake dry.

(2) Put in your reds next, and your yellows last, baking after each one.

(3) You can paint all over a slide with all sorts of colours, without baking in between each application, if they do not touch each other. Small detail in various parts of a slide, such as a large group, can be painted all at the same painting, if you don't let separate colours touch each other.

(4) Never try to paint over a colour until it has been baked dry. It cannot be done.

(5) You will save time by following these directions exactly and by trying the slides in the lantern until you get a good idea of how dense they ought to be—it is impossible to judge by the eye until you have had considerable experience.

(6) Much time is saved by painting several slides at once—putting in all that is possible on each and then baking them all at once. Painting single slides except at first is a terrible time-killer. It takes no longer to paint a dozen slides with oils than with water colours, except that all of one colour is put in at once with oils, and with water colours you paint the slide with all the colours at once.

MARCUS G. LOVELACE, M.D.

LITERATURE OF AERIAL PHOTOGRAPHY.

When M. L. P. Clerc delivered the Traill-Taylor Memorial lecture on aerial photography he appended to it on publication in the Journal of the Royal Photographic Society a bibliography of this new branch of photographic technics. In the ordinary course we cannot devote space to bibliographical compilations such as this, which to many of our readers, as we realise, are so much dead weight. In the present instance, however, we make an exception to this rule, on account of the very great value which this detailed analysis of the origins of aerial photography should have for historians, inventors, patentees and others in the future.

It is to be observed that the list does not include the works mentioned in M. L-P. Clerc's "Applications de la Photographie Aérienne" (Paris, 1919), or in the bibliography reprinted p. 682 of the "B.J." (vol. 68, November 5, 1920, No. 3,157).

The date in brackets given for each patent is that of the first application under the International Convention.

FORTHCOMING EXHIBITIONS.

1922.

January 11 to 27.—Camera Portraits, entitled "Men of Mark," by Walter Stoneman, at the house of the Royal Photographic Society, 35, Russell Square, London, W.C.1.

January 21 to February 4.—Partick Camera Club. Particulars from the Hon. Secretary, James Whyte, 51a, Peel Street, Partick, Glasgow.

February 11 to 25.—Scottish Photographic Salon. Latest dates, entry forms, January 23; exhibits, January 31. Particulars from the Secretary, James F. Smellie, Braefindon, Allanshaw Street, Hamilton.

February 14 to 17.—Exeter Camera Club. Latest date for entries, January 30. Particulars from C. Beauchamp Hall, Hon. Exhibition Secretary, Exeter Camera Club, "St. Denys," Bellevue Road, Exmouth.

February 18 to March 4.—Edinburgh Photographic Society. Latest dates, entry forms, February 4; exhibits, February 9. Particulars from the Hon. Secretary, G. Massie, 10, Hart Street, Edinburgh.

March 8 to 9.—Birkenhead Photographic Association. Latest date for entries, February 25. Particulars from the Exhibition Secretaries, Messrs. Longstaff and Trace, 33, Hamilton Square, Birkenhead.

March 28 to April 1.—Hackney Photographic Society. Hon. Secretary, Walter Selfe, 24, Pembury Road, Clapton, London, E.5.

April 5 to 8.—Leicester and Leicestershire Photographic Society. Particulars from the Hon. Secretary, W. Bailey, Cank Street, Leicester.

May 1 to 6.—Photographic Fair. Horticultural Hall, Westminster. Secretary, Arthur C. Brookes, Sicilian House, Southampton Row, London, W.C.1.

Patent News.

Process patents—applications and specifications—are treated in "Photo-Mechanical Notes."

Applications, December 12 to 17 :—

CAMERAS.—No. 33,643. Photographic cameras. E. Fisher.

PRINTING-FRAMES.—No. 33,974. Photographic printing-frames. H. W. Harrington.

FOCUSSING-DEVICES.—No. 33,901. Focussing-devices for photographic apparatus. J. Krone.

STEREOSCOPY.—No. 33,363. Means for obtaining stereoscopic effects on photographic plates, films and prints and projections therefrom. H. Newbold.

PHOTO-SCULPTURES.—No. 33,600. Means of producing sculptures and reliefs from photographs. E. J. Clifford.

PROJECTION APPARATUS.—No. 33,680. Optical projectors. A. A. D. Lang and A. D. Lang, Ltd.

PROJECTION APPARATUS.—No. 33,346. Producing pictures by projection. E. J. Marston and H. A. Smith.

PROJECTION SCREENS.—No. 33,344. Screens for exhibition of projected pictures. E. J. Marston and H. A. Smith.

OPTICAL PROJECTION.—No. 33,334. Optical apparatus for projecting pictures, reading matter, etc. J. T. Tussaud.

CINEMATOGRAPHY.—No. 33,406. Apparatus for exhibiting cinematographic pictures, etc. J. W. Hasselkus, H. Moore, and Ross, Ltd.

COMPLETE SPECIFICATIONS ACCEPTED.

These specifications are obtainable, price 1/- each, post free, from the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C.

The date in brackets is that of application in this country; or abroad, in the case of patents granted under the International Convention.

STEREO-CINEMATOGRAPHY.—No. 159,991 (December 10, 1919). The apparatus provides for the photographing of scenes wherein two moving picture films are placed parallel one to another and are exposed simultaneously by the operation of a single handle. After the films are developed they are placed in projecting machines which project the individual exposures of the films on to substantially the same space of a screen. The individual exposure of one film as projected is followed by the individual exposure of the other film which was taken at the same time as the first individual exposure. The observer is provided with an optical box which will allow the observation of these alternately pro-

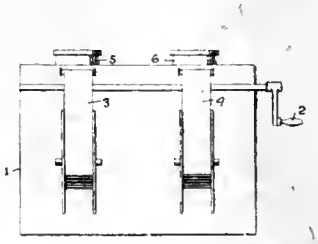

Fig. 1

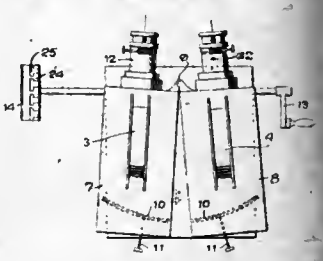

Fig. 2.

jected exposures so that one eye of the person will perceive the projections of one film and the other eye will perceive the projections of the other film. Certain connections between the optical box and the projecting machine provide for the operation of the various parts of the optical box in synchronism with the operation of the projecting machine.

In the drawings, the camera 1 is shown with the handle 2 which operates the camera to expose simultaneously films 3 and 4. The films placed are shown as parallel, and, when exposed, are substantially in the same vertical plane. Good results have been obtained by this method but various modifications of apparatus and positions are possible. These films will be marked "right" and "left" or any other distinguishing mark which will deter-

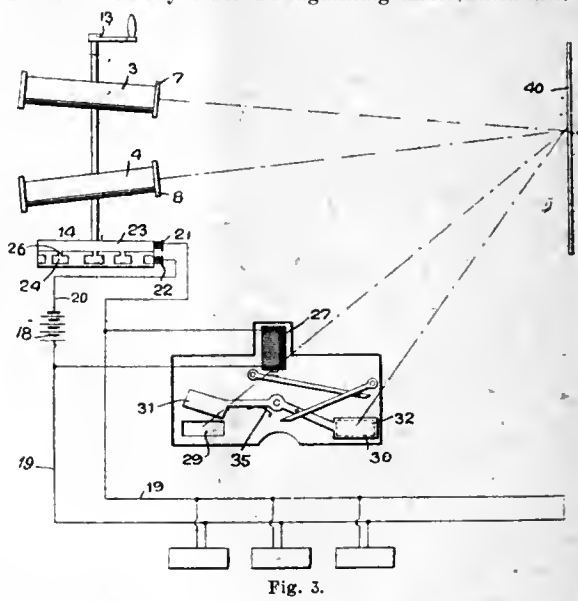

Fig. 3.

mine the position in which they were located during the photographing of the scenes. This will provide means by which the films may be properly placed in projecting machines.

In projecting the pictures, as recorded on films 3 and 4 to produce the stereoscopic effect, individual exposures of a film are projected alternately on a screen and on substantially the same area of the screen. It is, however, possible to produce a satisfactory picture when the centrelines of the projected pictures are not coincident on the screen. These centrelines may vary considerably. A projecting container operating two films at the same

time is illustrated in fig. 2 where films 3 and 4 are shown in position in machines 7 and 8 respectively, which are pivoted at 9 and may be oscillated about this pivot by means of racks 10 and pinions operated by thumb screws 11. These machines are provided with the necessary projecting portions 12 which are telescoping in order to obtain the proper focus. Any desired rack and pinion arrangement or other apparatus may be used for telescoping the parts of the projecting portions. The containers 7 and 8 may be oscillated about pivot 9 in order that the projections of the films may be thrown on to the same portion of a screen. The handle 13 is employed to move the necessary operating parts of the projecting machines and any form of universal

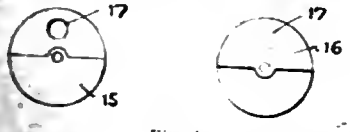

Fig. 4.

joints may be employed to allow the oscillation of the projectors. Mounted on the operating shaft is the electrical circuit interrupter or commutator 14. Referring to fig. 4, the two shutters 15 and 16 which are used on the projecting machines and their paths of revolution are illustrated. The exposures on the films are projected through holes 17 and the shutters cover and uncover the holes alternately. Generally, the shutters are made semi-circular, but the contour of the straight edges across the centre may be changed so that the projection of an individual exposure of one film may be thrown on to the screen a little after a projection of the other film has been cut off.

An electric circuit and necessary electromagnets have been employed to operate the parts of the optical box and reference is made to figs. 3, 5, 6 and 7 in connection with the electrical system as herein employed. The battery 18 provides the necessary electrical power and has the leads 19 and 20 therefrom which are connected to the brushes 21 and 22 respectively. These brushes contact with the electrical circuit interrupter or commutator 14, the brush 21 pressing against the continuous annular conducting metal 23 and the brush 22 contacts with electrical conducting segments 24, which are mounted in any well-known insulator 25 and are connected by conductors 26 to conductor 23. Connected in parallel with this circuit are various electromagnets 27 which are excited when the brush 22 contacts with one of the segments 24 as there is a complete electric circuit from battery 18 through lead 19, brush 21, annular conductor 23, lead 26, segment 24, brush 22, lead 20, back to the other connection on the battery 18. There can be a large number of optical boxes placed in the electrical circuit.

The optical viewing boxes as illustrated in fig. 7 are made of any light material and are employed to be placed in front of the eyes and they are recessed at 28 for receiving a portion of the observer's nose. The boxes are provided with openings 29 and 30 which may take the form of circles or slots, the latter being preferable in order to accommodate the average range of distances between eyes of various people although other means may be employed to allow for the varying distances between the eyes. The operating parts as designed and illustrated show that opening 29 has cover 31 and opening 30 has cover 32 for covering and uncovering these openings. The covers are mounted on rocker

Fig. 6.

Fig. 5.

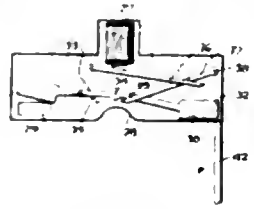

Fig. 7.

arm 33 pivoted at 34 and held normally in position with opening 29 uncovered by means of spring 35. The electromagnet 27 when excited draws upward arm 36, which in turn carries arm 37, about its pivot 38; this arm 37 contacting with rocker arm 33 at stud 39. When arm 36 carries arm 37 upward, the rocker arm 33 is moved against the spring 35 and opening 30 is uncovered while opening 29 becomes covered. The design of the operating parts in the optical box may be varied in any desired manner; the main object being to cover and uncover the openings alternately.

In fig. 3 the centrelines of the projected pictures are shown as meeting on the screen 40 at 41 and the scenes projected may be observed from any position of the theatre; in this particular diagram there is shown an enlarged optical box as being operated at the right of the projecting machines. The position of the shutters as shown in fig. 4 will be considered as being the position of the shutters in projecting machines 7 and 8 of fig. 3, the shutter 15 being located on projecting machine 7. For purposes of description it will be considered that the optical box is held by an observer so that the opening 29 will be in front of the left eye. Since this opening is uncovered and the shutter 15 is not obstructing the projection from projecting machine 7, the observer will see a certain scene with his left eye. As the operating crank 13 is rotated, the brush 22 will contact with one of the segments 24 and thereby complete the electrical circuit from the battery through the commutator and the electromagnet, which in turn being excited will move the operating parts of the optical box and uncover opening 30 and cover opening 29. At the same time shutter 15 is moved in front of opening 17 on machine 7 and shutter 16 uncovers opening 17 on machine 8 so that the scene on film 4 will be projected on screen 40 and will be seen by the right eye of the observer.

It is well known in the moving picture art that individual exposures will not be clearly projected unless moved at a rate of speed greater than about 16 times per second. It is found that by projecting alternately the two films on the same area of the same screen the individual exposures of pictures which have been photographed simultaneously and having one eye observe projections made by one projecting machine and the other eye observe projections made by the other machine, that the image of a scene will be retained by one of the eyes and the image impressed upon the other eye will, in connection with the retained image, form the picture as actually enacted and as it would have been observed by the observer's eyes had he been on the scene; and this composite image will be appreciated as though the observer was present at the actual scene. Observations of moving pictures by the use of the optical box are desirable to produce more effectively the stereoscopic effect and if desirable the openings in the box may have magnifying glass or lenses as desired.—Ramon Gantes Arestizabal, Van Court Inn, Roselle, New Jersey, U.S.A.

Trade Names and Marks.

APPLICATIONS FOR REGISTRATION.

DUPLI-TIZED.—No. 420,051. All goods included in Class 39. Kodak, Ltd., Kodak House, Kingsway, London, W.C.2, dealers in photographic materials. October 31, 1921.

MARKS PLACED ON THE REGISTER.

The following marks have been placed on the register:—

KOTINIC.—No. 418,037. Flashlight powders and other preparations for flashlight purposes, all being for use in photography. Kodak, Ltd., Kodak House, Kingsway, London, W.C.2, dealers in photographic materials.

KALO.—No. 418,129. Photographic paper, photographic albums, and photographic mounts included in Class 39. Ilford, Ltd., Britannia Works, Roden Street, Ilford, Essex, manufacturers of photographic plates, paper and films.

TELERADIOGRAPHIC WORK.—Some experiments have been carried out by a Commission appointed by the French Academy of Sciences to determine how far under differing conditions X-rays can penetrate. The tests were radiographic, and in one instance a negative was taken at a distance of 6 ft. from the X-ray tube, the rays having to penetrate 1 in of lead, a marble slab, some wooden boards, and a floor 12 in. thick, and yet these rays were no stronger than those commonly used in X-ray photography. With the same strength a photographic plate was reached by rays after passing through a brick wall 20 in. thick, and a radiograph of a skull taken at a range of 85 yarda is comparable to one taken at short range. With a much more powerful ray than is commonly used in radiography these experiments proved that negatives could be taken at hundreds of yards' range. The long-distance radiographic experiments were carried out in two buildings, one on either side of a city square, with a distance of 85 yards between them. This space was traversed by the X-rays, and the result was negatives from which good prints were made of a skull, a bottle, a crab shell, and other objects. This long-range X-ray photography has been called "teleradiography."

New Books.

Photographic Abstracts. Vol. 1. Edited by B. V. Storr, M.Sc., F.I.C. Royal Photographic Society. 10s. net.

THE publication of the fourth quarterly part of "Photographic Abstracts," by its completion of the first volume of this commendable enterprise of the Scientific and Technical Group of the Royal Photographic Society, invites all the attention which can be directed to the services which have thus been rendered to the photographic student, experimenter and inventor. The complete volume, although it consists of only 163 pages, contains abstracts of photographic communications, patent specifications, etc., which reach the number of 871. This latter figure, however, by no means represents the number of individual pieces of subject matter which have come within the survey of Mr. Storr and his colleagues, for one meets with compound abstracts which include many separate items. There is, for example, in Part 4, one which is a list of patent specifications occupying more than three closely-printed pages. The result of the year's work has been to bring within a small compass the means of ascertaining the main outlines of practically every paper which has been published during the past twelve months on the various branches of photography, and on those departments of chemistry and physics relating to it. That is a very important work, the further prosecution of which is deserving of every encouragement. Inasmuch as the abstracts in each issue of the publication are arranged under one or other of eleven descriptive headings, there is not the necessity which there is in a less systematically compiled work for a subject index. We can readily understand that Mr. Storr could hardly contemplate as desirable or possible the compilation of such an appendix. However, he has done the next best thing by providing the volume with a name index, which itself occupies five pages. Those with any experience in the tracing of subject matter in scientific literature will acknowledge that the name index often provides the most certain clue, since it can be compiled with a precision which no subject index can equal. Mr. Storr and the publication committee, Messrs. K. C. D. Hickman, E. K. Hunter, T. Slater Price, and F. F. Renwick, are to be congratulated on the completion of the first year of their exacting labours. They have established on a solid foundation a work which inevitably must grow in importance with the development of photographic processes from the technical and scientific standpoints.

Pictorial Landscape Photography. By The Photo Pictorialists of Buffalo. Boston: American Photographic Publishing Co., 428, Newbury Street. 3.50 dollars.

THE amateur in pictorial photography in the United States is nothing if not serious. One has only to think of Mr. Stieglitz's intense career to realise that. Members of the Buffalo Camera Club seem to be particularly serious. If we understand the first sentence of the preface to this work correctly, they regard the formation of a "pictorial group" within this club as approximately the beginning, in the year 1905, of pictorial photography in America. In that view we think they are somewhat too serious. The Stieglitzes and Steichens, Clarence Whites and Holland Days, had surely made American pictorial photography known in other countries before the light of art began to radiate from Buffalo. Some of us remember the mild sensation which was created in this country when the late Snowden Ward introduced the "American School" to us. Members of the Buffalo "pictorial group" may have been represented in it; we are afraid we do not remember, but we are inclined to think that the striking and beautiful work which Mr. Porterfield has shown here is of later growth. However, this is all beside the fact that the pictorial photographers of Buffalo have now thought it well to embody their pictorial practice definitely in print, and the present volume, written by them collectively, is the result. An admirable project certainly, yet it is not easy to discover wherein precisely their text differs in its general character from other works on the same subject. Apparently our Buffalo friends are essentially landscapists, and are of the view that the broad, open effects at which they aim are best secured by pigment printing, either carbon, gum-bichromate, or a combination of the latter with bromide printing. Here they have much in common with the saner exponents of pictorial photography in Germany. They have strong views on the amenities which should be observed in the making of prints, but we fear they depart from historical accuracy in repudiating with some heat the American origin of the method of multiple mounting, which reached its technical zenith at the hands of Mr. Frederick H. Evans. Therefore, it is really too bad of them to disparage the practice by reference to a particular example of Mr. Evans's. But this is the only item which calls for challenge in the many pages of the book. Pictorial photographers will certainly be interested in what the Buffalo pictorialists have to say, and to show in the shape of numerous plate reproductions of their work.

Optic Projection. By Simon Henry Gage and Henry Phelps Gage. Ithaca, New York: Comstock Publishing Co. 5 dols.

IN this large manual of over 700 pages the authors have treated the subject of optical projection with a degree of comprehensiveness and a superabundance of detail which has not previously been allotted to the subject in any text-book in any language. They include within the scope of their text not only ordinary lantern projection, but the use of the projection microscope, cinematograph projection, and the employment of projection systems for the purpose of making drawings, the latter a branch of work for which many special appliances have been designed, chiefly by Continental constructors. Throughout, these various branches of projection are dealt with fully from the practical standpoint, and particularly in respect to the methods and precautions incidental to the use of electric current as the source of light. The authors are evidently trained scientific men, and it is equally evident that they are thoroughly familiar with the practical employment of the innumerable instruments which they describe. Their manual gains a very great deal in practical usefulness by the numerous detailed descriptions and drawings of actual appliances on the market. These are chiefly those by American constructors, but the models of British and Continental firms come in for a full share of notice.

In arrangement the manual is highly sub-divided into numbered paragraphs, the cross references from one to another of which must have entailed a great deal of extra work. Also, each of the twelve chapters which deal with practical manipulation has appended to it a table summarising the things which it is of chief importance to observe or avoid for successful practice. In those dealing with the ordinary optical lantern, chief attention is given to the use of direct or alternating electric current, and the difficulties to be overcome in employing arc lamps with the latter specially considered. The practical details of every form of light-source are the subjects of special sections, in which we can discover only one omission, namely, the pastille system of employing oxy-acetylene, which no doubt was introduced in practical form after the authors had completed their text. The lanterns for the projection of opaque objects and of objects in a horizontal plane occupy a special chapter, in which are described the instruments ranging from the elaborate epidiascope to the cheap lanterns sold for showing postcards, etc., on the screen. Micro-projection is one of the chief parts of the book, in which the importance of correct adjustment of illumination is specially considered. Incidentals are so fully treated in other places that the chapter on cinematograph projection is shorter than might be assumed, and is largely confined to the special conditions as regards handling of film and avoidance of flicker. In considering the arrangement of a projection theatre, the authors deal very thoroughly with the balance of advantage between screens having a completely diffusing surface and those producing partially specular reflection. They discuss the relative merits of these screens from the points of view of college lecture theatres and those for commercial cinema shows. One point which is not touched upon is the relation of the arrangement of the auditorium as regards designating those parts of it where the audience obtains the best perspective rendering of the projected scene. We think it was a German professor who some years ago, in giving formulæ for calculating these places in the viewing space, insisted that the prices charged for admission should be upon a corresponding scale. We fear that a public which exhibits such indifference to the character of the subjects which it pays to see is not very susceptible to refinements of perspective. Messrs. Gage's treatise contains a chapter on electric currents, lamps, wiring and measurements, which is in itself a manual of the electrical knowledge which the lanternist should have. Concluding pages contain a brief historical summary of the evolution of projection, a directory of manufacturers and dealers in projection appliances, an alphabetical list of the chief works on projection, and a comprehensive index worthy of the enormous mass of technical information contained in the volume.

New Materials.

ENSIGN POWDER MOUNTANT.—Messrs. Houghtons, 88-89, High Holborn, London, W.C.1, have just introduced a mountant in the form of a powder, which has simply to be mixed with cold water in order to form a mountant ready for use. We dare say that in this age, when manufacturers conspire to relieve the amateur photographer of every occasion for thought or trouble, there is an advantage in a mounting mixture which is even easier to prepare than starch paste. Certainly nothing could be simpler than the preparation of this mountant, which we find to make a beautifully smooth and adhesive paste, resembling well-made starch mountant in its behaviour. We have no hesitation in commending it to the amateur worker, who will find that there is nothing to complain of in the tenacity with which prints adhere to the mounts. The paste is supplied in tins, price 1s.

Meetings of Societies.

MEETINGS OF SOCIETIES FOR NEXT WEEK

MONDAY, JANUARY 2.

Bowes Park and Dist. P.S. "The Valley of the Arno." W. E. Walker.
Bradford Photographic Society. Whist Drive.
Forest Hill P.S. Print and Lantern Slide Competition.
Kidderminster P.S. "Through the Grecian Archipelago and the Near East." W. Butcher and Sons.
Leeds Camera Club. Annual Outing.
Optical Society. Exhibition of Scientific Instruments.
South London P.S. "Telephotography." T. W. Derrington.
Walthamstow and Dist. P.S. "Personality in Pictorial Photography." E. W. Brooks.

TUESDAY, JANUARY 3.

Belfast C.P.A. Camera Club. "How a Reflex Camera is Made."
Exeter Camera Club. Affiliation Competition Prize Slides.
Hackney P.S. "How a Reflex Camera is Made." W. Butcher and Sons.
Morley Photographic Society. Whist Drive.
Mottingham P.S. "A Loan in London." W. L. F. Wastell.

WEDNESDAY, JANUARY 4.

Catford Camera Club. "The Value of Failure." E. C. Perry.
Croydon Camera Club. "Chemical Methods in Photography." C. M. Thomas.
Dennistoun Amat. P.A. A Movie Night. W. S. Shepherd.
Edinburgh P.S. "The Gentle Art of Control." E. F. Spaven.
Leicester P.S. Ladies' Night. Social and Concert.
Partick Camera Club. "Through the Grecian Archipelago." W. Butcher and Sons.
Rochdale Amat. P.S. A.P. and P. 1921 Prize Slides.
South Suburban P.S. "Psychic Photography." Society for the Study of Supernormal Pictures.

THURSDAY, JANUARY 5.

Gateshead Camera Club. Social.
Hammersmith Hampshire House P.S. "Dark Room Dodges." G. C. Weston.
Ilford Photographic Society. Dance.

FRIDAY, JANUARY 6.

Wombwell P.S. "Colour Photography." C. B. Howdle.

CROYDON CAMERA CLUB

Mr. A. C. Braham, of the Autotype Co., paid one of his ever welcome visits with a demonstration of "Carbro," including the latest modifications and improvements which add to certainty and ease of working. The procedure having been fully outlined in a recent report of a demonstration at the R.P.S. need not be referred to again.

However, there are a few points which may usefully be mentioned. Those who have the printed instructions should substitute "waxed paper" for "blotting paper" mentioned on page 2, and note that a weight is superfluous. Mr. Braham never uses one. It was also interesting to hear that a Carbro records more gradation than the eye can see in a bromide print, invisible gradation in the high lights, and buried detail in the shadows appearing for the first time in the carbon picture and adding greatly to its beauty. For the best results a vigorous and somewhat over-developed bromide print is desirable. Members expressed the most appreciative opinions regarding the process, especially its capacity for alteration in any desired direction.

The week before, the secretary, Mr. J. M. Sellors, showed some instructive tests made by him, with a device for softening definition brought forward some time ago, and then stated shortly to be placed on the market. No doubt ultimately it will get there. A series of densities and a negative were employed, from which bromide paper enlargements were made.

The device consists of a photographically-produced image on glass of fine black lines crossing each other at right angles, and protected by a cover-glass, the contrivance being placed on the lens like a cap. The enlargements showed a pleasing diffusion, perhaps slightly too pronounced for some tastes, closely resembling that afforded by Mr. H. P. C. Harpur's original method of placing separated layers of black or white tulle, of about 1/16-in. mesh, in front of or behind the lens. (The degree of separation is not important, ¼ in. works well.) Mr. Harpur maintains that white tulle gives slightly less contrast than the black, which is denied by Mr. Sellors. One deplores the lack of observation in the other, who, in turn, attributes the alleged difference purely to a softening of the perceptive faculties.

In each case three exposures were made: One with no diffuser; one with six layers of white tulle placed behind the lens; and one with the glass diffuser in front of the lens; the exposures respectively being in ratio 1 : 2 : 3. The latter two seemed a shade more exposed than the first exposure; and slightly less contrast and slightly more diffusion existed in the second compared with the third.

In the discussion Mr. A. F. Catharine said that the irregular structure of tulle gave diffraction in all directions, which was what was wanted. With the regular square formation of the glass diffuser he would expect star-like radiation. In his opinion a more pleasing diffusion was obtained in direct portraiture, and in the making of enlarged negatives, as then the high-lights spread into the shadows, whereas in direct enlargements the reverse held. Mr. L. J. Hibbert said that the diffusion produced by each transparent square on the glass device was in the nature of a disc, not a star.

Mr. Harpur said not only was the tulle irregular, but it possessed fine fringes, which enhanced its virtue in the desired direction. The idea of using tulle in front of the lens occurred to him many years ago at the Zoo, when observing the wire-netting of the cages in the monkey-house. In reply to a question he stated that his observations were made from the outside of the cages. Recently he had tried imparting a vibratory motion to the tulle and would communicate results later.

Mr. E. A. Salt said that by a curious coincidence he had just thought of mounting the tulle in swinging pendulum fashion, and in strict confidence had imparted this brain-wave to the president. He had been implored to preserve strict silence by Mr. Keane, who, it transpired, was experimenting with the fabric mounted on a rotating wheel. A combination of the three methods should meet the most exacting requirements. Mr. Sellors agreed, but expressed the opinion that a tennis racket waved in front of the lens would equally meet the case.

News and Notes.

DEATH OF MR. C. W. BURROWS.—We regret to have to announce the death of Mr. C. W. Burrows, a very well-known member of the United Stereoscopic Society, who died on December 24, 1921, age 68. He had been in failing health for many years, but up to the last maintained his great interest in stereoscopic work, and will be very much missed by the members of the U.S.S.

FOUR THOUSAND NEGATIVES OF SNOWFLAKES.—Mr. W. A. Bentley, of Jericho, Vermont, U.S.A., an American scientific journal states, has spent the best part of the past thirty-five winters photographing snowflakes, and his collection now consists of four thousand negatives, and no two are alike. This labour has all been done with a primitive photographic and microscopic apparatus. He was, we are told, the first to devise a means whereby a snowflake could be photographed and enlarged with exactness with such simple equipment. The rigorous winters of his native State were, of course, in his favour. But, even in the intense cold of Vermont, great speed is required in this work, for, once a snowflake is isolated, although there may be no danger whatever of melting, it is subject to evaporation, a process that is just as destructive, in the case of such a fragile object as one flake of snow.

ENLARGING DENSE NEGATIVES.—Messrs. Hewittic Electric Company, Limited, 80, York Road, King's Cross, London, N.1, write:—"We notice in your "Answers to Correspondents" that you have had an inquiry from a reader who is anxious to know the best form of lighting for dealing with dense negatives. As you are doubtless aware, we are manufacturers of a mercury-vapour type of lamp which is largely used by the leading trade houses for enlarging work, and the general opinion of these users is that it is the best known form of illuminant for this class of work. We have also a small quartz type of mercury lamp coming into use, particularly where small dense negatives have to be dealt with. If any of your readers are interested we shall be pleased to demonstrate these outfits to them at the above address.

Answers to Correspondents.

In accordance with our present practice a relatively small space is allotted in each issue to replies to correspondents.

We will answer by post if stamped and addressed envelope is enclosed for reply: 5-cent International Coupon, from readers abroad.

Queries to be answered in the Friday's "Journal" must reach us not later than Tuesday (posted Monday) and should be addressed to the Editors.

B. T. G.—If there had been anything of the kind we think we should have heard of it. We always regard these reports with a good deal of suspicion. As a rule, the lay Press is very imperfectly informed on photographic matters, particularly on colour photography.

M. S.—As the photographs were taken to your customer's order, the copyright in the prints is solely your customer's property. You are not entitled to any reproduction fee, and if you had submitted photographs you would simply have been offering to sell something that you haven't got.

A. A. E.—For the general account of the origin and principles of photographic processes there is no better book than "Photography of To-day," by Chapman Jones. It chief chapters are on light, lenses, colour, colour photography, motion photography, and reproduction processes. Our own publishers supply it, price 9s. 6d., post free.

F. K. L.—Yes, if you divided the focal length of the lens by the *f* number, the result (providing the *f* numbers are correctly marked on the lens) is the diameter of what is generally called the "effective aperture" or "entrance pupil." In the case of any lens which has a positive element in front of the diaphragm aperture, this diameter is slightly larger than the actual diameter of the stop.

P. H.—The features you describe are fairly common among enlarging apparatus. On looking at advertisements and catalogues of 15 and 20 years ago we see that they figure in a number of commercial enlarging lanterns. We think the best thing you can do is to look through the advertisements of past volumes of the "B.J. Almanac," which you can see in the library of the Patent Office, 25, Southampton Buildings, Chancery Lane, W.C.

E. G. P.—You can have a negative lens fitted to your R.R. so as to give an image twice the size at the same camera extension, but the F. No. will then be twice its value for any particular stop, e.g., *f*/8 will be *f*/16, and the exposure will be four times. So far as we know there is no means of obtaining an equivalent focal length half the camera extension, and, at the same time, preserving the full working speed of the positive lens. The North Middlesex Photographic Society meets at Mount View Congregational Church, Stroud Green. It is one of the best of the societies in London, and is no doubt sufficiently accessible to you. The secretary is E. C. Ridge, 88, Ambler Road, Finsbury Park.

P. T. M.—The belief that a process of photography was invented by James Watt in conjunction with his partner, Matthew Boulton, towards the end of the eighteenth century, attracted a good deal of interest many years ago, but a very full investigation which was made by the Royal Photographic Society about the year 1863 showed that the claim could not be substantiated. We had some articles on this subject in the "B.J." of January 12 and January 19, 1917, on the occasion of the claims being revived in the daily Press in connection with the death of the son of Fox Talbot. If you look up Vol. I. or Vol. II. of the "Photographic Quarterly," you will find an article on the same subject by W. Jerome Harrison, who, as a Birmingham man, had special opportunities of examining the evidence.

G. W. C.—A hypo bath can be made considerably more rapid in action by adding to it a certain proportion of ammonium chloride (sal ammoniac). A formula for a bath of this kind is—hypo, 4 ozs.; ammonium chloride, ½ to 1 oz.; water, 20 ozs. This bath will fix in about half the time of one made up without ammonium chloride. We do not think there is any real advantage in such extra-rapid fixation. It is of service in making negatives in the shortest possible time, as, for example, in while-your-wait portraiture at bazaars, or under other conditions where a print is required in a few minutes. We do not recommend it for general use, because a bath of this kind is less likely to fix satisfactorily as it becomes exhausted than one which is made up with hypo only or with hypo plus the usual constituents of an acid fixing bath.

COPYRIGHT IN SIMILAR SUBJECTS.—I recently made some photographs for a local firm, to be used as advertisements. They had to be of a girl holding certain goods in her hand. I engaged a model specially for the job, and after I had taken the photographs for the advertisements, I took a few negatives for myself. Of course, the model wore the same costume as for the others. Having made several enlargements from the latter negatives and shown them in my window, I have been told by the firm that they object to the exhibition of them, as the pictures were made to their order, and therefore the copyright is theirs. I ought to add that I made a charge (separately on the invoice) of 10s. 6d. for the services of the model.—G. F. S.

You should have sent us a pair of the photographs. If those which you made subsequently are altogether different in pose from those which you made for the firm, there cannot be any objection to your showing them or making other use of them. We suppose that the objection of the firm must be based on some close resemblance between the photographs you made for them and those which you made for yourself. If that is so, a very delicate point of copyright law is involved. Strictly speaking, under copyright law, there is nothing to prevent you making a second negative identical with one which you made for the firm and regarding the former as your own copyright. But we think this view, while it may not conflict with the letter of the Copyright Act, is opposed to its intention, and we certainly believe that in these latter circumstances the firm would be able to restrain you from making use of a photograph which, for practical purposes, is indistinguishable from the one which you made for them.

MONTHLY SUPPLEMENT

ON

Colour Photography.

CONTENTS.

A FORGOTTEN PAGE IN THE HISTORY OF COLOUR PHOTOGRAPHY.

I was always under the impression that Hillotype was a big swindle, and this idea seemed to be prevalent also elsewhere, if one may judge from the following definition from Cassell's "Encyclopedia of Photography," 1911, p. 293. "An alleged process of photographing in colours claimed to have been invented by the Rev. Levi L. Hill, of Westkill, New York State, in 1852." Quite recently I have acquired a copy of Hill's book, entitled "A Treatise on Heliochromy, or the production of pictures, by means of light, in natural colours. Embracing a full, plain, and unreserved description of the process known as the Hillotype, including the author's newly-discovered Collodiochrome, or natural colours on collodionised glass. Together with various processes for natural colours on paper, velvet, parchment, muslin, porcelain, wood, etc., and elaborate essays on the theory of light and colours, the chemistry of heliochromy, and the entire range of the author's nine years' experience in sun colouring. By L. L. Hill, of Westkill, Greene County, N.Y. Published by Robinson and Caswell, 57, Chambers Street, N.Y. 1856."

The work is an octavo volume of 175 pages, and was originally adorned with three photographs—of the house, the village, and the author—but these are missing from my copy. The first 37 pages are an account of his life, which is rather funny reading in spots. Then we have a treatise on light and colour, which proves that at least the author had some conception of his subject, and that he was fairly well acquainted with the work of others is proved by the fact that he sums up, though rather cursorily, the work of Biot, Daguerre, Nicephore, Niépce, Sir John Herschel, and Sir (sic) Robert Hunt, Scheele, Bérard, Seebeck, Berthollet, Sir Wm. Herschel, Talbot, Niépce de St. Victor. Twenty-four pages are filled with quotations from daily papers, photographers and others, including the U.S. Senate, as to the beauty and perfections of his results. With regard to Niépce's work, he speaks in no uncertain terms, for on p. 98, after quoting Niépce's paper in full, from the London "Athenæum," he says "the reader may judge how far M. Niépce is entitled to credit for originality. After all the fuss that has been made about his great discovery, I, for one, can see but one original idea in it, namely, the imaginary relation between the action of the coloured rays and the colours of certain flames. The idea of chloridising a silver plate he borrowed from Becquerel. He owns this in his memoir. What then has he originated? Here is the indisputable answer:—He has originated the use of various chlorides, for doing what Becquerel did with a few chlorides. I defy any man of sense to make any more than this out of his famous 'Memoir.' Yet this document has been paraded before the public in the natural colours which usually embellish envy and spite, with a view to depreciate an American invention. This has been done by men who became my enemies because I would not become their bosom friend, and let them have a bite at the loaves and fishes."

His notes on the natural and artificial colorific agents is decidedly good reading, and he seems to have been fairly well acquainted with the action of light on the silver salts. His methods for producing colours on "collodio-chrome" and on velvet, etc., are quite feasible, and are practically nothing more than the Seebeck process, and he had the ingenious idea of obtaining silver in a fine state of division by collodionising a plate, exposing to light, developing and fixing, and then chlorising.

In Chapter 14 he describes in full his process, and it would seem to me that it really deserves to be rescued from the class of swindles and placed amongst the true heliochrome processes. In order that those interested may judge for themselves, this chapter is printed verbatim:—

This name—"The Hillotype"—was first given to my process by S. D. Humphrey, Esq., editor of the "Daguerrian Journal." He did so on his own responsibility. I called it, from the first, "The Heliochrome." Mr. Humphrey's godfathership has, however, been universally adopted by the public. I am now to detail the process known by Mr. Humphrey's cognomen, and will do so.

I.—As a Formula.

1. Thoroughly clean a good Daguerreotype plate by means of rotten-stone and alcohol. Polish with buckskin and calcined lampblack. Rouge is detrimental. For ordinary experimenting you may omit the polishing.

2. Electrotype the plate till its surface assumes a deep blue. The ordinary cyanide of silver solution is far inferior to the following:—Mix solutions of the cyanides of silver, copper and zinc, in the proportion of 8 parts of silver, 2 of copper, and 1 of zinc. Use two pairs of Daniels batteries, and proceed in every other respect as for electrotyping an ordinary Daguerreotype plate.

3. Rinse and dry the plate. If you use artificial heat to dry the plate let the latter get cold before the next operation.

4. Place the plate on a level support, and cover it with a well-filtered solution of nitrate of mercury—1 grain of the salt to 20 ozs. of water. Let this remain on about half a minute. Pour it off and thoroughly rinse the plate, then cover it with a solution of sel d'or (hyposulphite of gold),

20 grains to one quart of water, and let this remain on the plate for about one minute. Rinse and dry, and again place the plate in the silver solution until it is slightly changed—say, from one to five minutes—according to the strength of the solution. Rinse and dry, and buff to a polish, using calcined lampblack instead of rouge.

5. Now coat the plate over a jar of chloride of iodine—1 oz. chloride to 8 ozs. water—until it assumes a bright pink colour. Expose the plate a moment to diffuse light, or place it in a camera directed to a white screen as long as you would for a portrait, and then place the plate over mercury, heat to 170 deg. Fah. for about three minutes. Wash with hyposulphite of soda, or, what is better, cyanide of potash, as you would for a Daguerreotype picture; rinse with water, and gild in the usual way with chloride of gold, or sel d'or. Rinse and dry. If you have exposed long enough to light your plate will now have a bluish cast, or solarisation, similar to overdone linen in a Daguerreotype.

The whole of the above process will occupy but little more time than is required for producing and finishing an ordinary Daguerreotype picture.

6. Expose the plate, prepared as above, in a jar of chlorine gas, until it takes on a faint yellow the second time. Keep the plate in this state in total darkness until wanted for use. It greatly improves by keeping. The chlorine for the above coating I conveniently procure as follows, viz.:—I wet several folds of cotton cloth with dilute sulphuric acid, and place them in the bottom of a deep jar. On these I spread one thickness of cotton flannel, dry, and over that I sprinkle about a teaspoonful of dry chloride of lime, and immediately close the jar. In a few minutes a sufficiency of chlorine gas will be evolved to coat the plate. The action will be mild and uniform.

7. Prepare the following "Singular Compound":—In a quart bottle place 4 ozs. of common salt, 4 ozs. of blue vitriol, each well pulverised, and add 16 ozs. of water heated to 122 deg. to 140 deg. Fah. Shake well for five minutes with the bottle well stopped. Set it aside to cool. When perfectly cold there should be a deposit of sulphate of soda. If there is not, place the mixture in an evaporating dish, and by means of a water bath slowly evaporate, until, on cooling, a deposit of sulphate of soda takes place. Then decant the clear liquid into a clean bottle with a wide mouth. Fit into the mouth of the bottle the beak of a lead retort. In the retort place 2 ozs. of fluoride of calcium, and 4 ozs. of sulphuric acid, and apply a gentle heat. The beak of the lead retort must dip into the liquid in the bottle, and the stem passed tightly through a well-fitted cork. In a few minutes the liquid in the bottle will become saturated with fluo-hydric acid. The fumes of this acid are intensely poisonous, and the operation should be conducted with extreme caution. When the operation is over let the retort cool, and immediately wash it with abundance of water. To preserve the liquid it should be transferred to a gutta-percha bottle. After the transfer add to the liquid 4 ozs. of pure muriatic acid, and ½ oz. black oxyde of copper. Cork tight, and let it stand at least 48 hours with occasional shaking. Now mix, in an evaporating dish, 1 oz. of peroxyde of iron (common rouge), 5 ozs. pure muriatic acid, and ½ oz. of yellow ochre, and apply heat until a deep yellow liquid is formed. Filter into a glass bottle, and add ¼ oz. of boracic acid, 60 grs. of phosphate of soda, 30 grs. of permanganate of potash, ½ oz. of the fuming liquid of Libavius (made by saturating nitro-muriatic acid with tin by the aid of heat), 5 drops of pure bromine, and 3 grs. of iodine. Agitate the mixture for about ten minutes, and add it to the other bottle. Shake well and filter. Place the clear liquid in a large earthen glass, or gutta-percha, platter, and keep it in sunlight till the watery portion has evaporated. The bottom of the dish will be covered with clusters of brilliant green, needle-form crystals. Collect, and keep these in a well-stopped bottle. When you wish to form a bath for coating plates dissolve 2 ozs. of these crystals in 4 ozs. of water, and add 1 oz. of pure muriatic acid, 1 grain of bichromate of potash, 3 grs. of sel d'or, and ½ oz. of hydrofluoric acid. Shake well and filter. Place this in an earthen glass, or gutta-percha, platter—tilt the platter so as to gather the liquid in one end of the dish, lay the plate prepared as in Sec. 6, on the bottom of the platter, and lower the latter in such a way as to secure an even flow of the chemical over the plate. Suffer the plate to remain from three or ten minutes, or until it appears nearly black. This should be done by the light of a candle only. Now rinse the plate freely with water, and dry it off with a spirit lamp, as you would finish a Daguerreotype. In this state the plate will reproduce the colours, by a prolonged exposure to light, as you will see by pressing upon it a coloured engraving by means of a plate of glass, and placing it in sunlight. Many of my experiments were performed in this stage of the process.

8. To render a plate, prepared as above, exquisitely sensitive, you have only to immerse it a few seconds in the following preparation, rinse and dry. In 1 oz. of aqua ammonia dissolve 6 grains of gallic acid, add to this 1 drachm of hydrosulphuret of ammonia, ½ oz. common salt, 1 drachm each of strong essence of lavender, cassia, and cloves, 2 drachms of grape sugar, 50 grains of fluoride of potash, 10 grains hyposulphite of copper, and a quart of water. This preparation may be used in a platter like the preceding. When not in use it should be kept well corked. Its use gave me a great step in advance. It not only quickens the process, but adds greatly to the strength and truthfulness of the coloration.

9. A further great improvement in the strength and brilliancy of the pictures results from modifying the coating of the plate, as above prepared, by the application of heat, or by the action of the orange rays of light, or by both combined. If the plate is heated until it assumes red, it gives the colours more brilliantly, and the whites are always good. A plate which would not give yellow and green will give both after being exposed under a deep orange glass, in the sun, for a few seconds.

10. In forming a coloured image on these plates direct, without a developer, a prolonged exposure is required—from five minutes to half an hour, in sunlight. Your true way will be to use the process thus, by means of superposing coloured engravings, or other transparent objects, until you have thoroughly tested your chemicals and mastered the process of coating. Then you may proceed to the work of developing the latent coloured images, which, you will soon be convinced, are formed almost instantaneously. Phosphuretted and sulphuretted hydrogen, and especially a mixture of carburetted hydrogen, phosphuretted ether, and ammoniacal gas, have the property of developing these images. So, also, with hot aqua ammonia, nearly saturated with hyposulphite of silver, and the combined vapours of burning copper, zinc, lead and antimony. I make an alloy of these metals, and vaporise this alloy in a mercury bath, heat over a small charcoal having a blast. The plate should be raised about 18 in. from the bottom of the bath. My apparatus for heating is an upright furnace, 10 in. in diameter. Attached to one side is a 2-ft. balance wheel over which passes a band which turns a small shaft, and gives a rapid motion to a fan wheel 8 in. in diameter. The wheel is in a hollow disc having an opening in its sides to let in air. This disc discharges the blast through a tube entering the furnace. A common bellows, of good size, will answer.

The ammonio-hyposulphite of silver, named above, I use in a platter, placed over heat. It must be used at the temperature of 150 to 160 Fah. The plate should be immersed in the liquid for a few minutes only. In this way I have produced some very fine results.

I use the mixed gases, above named, as follows. In a deep jar I place a few sticks of phosphorus, and cover them with sulphuric ether. The fume arising from it is phosphuretted ether. In the same jar I place a small bottle of aqua ammonia, and into the lower part of the jar I inject a small stream of carburetted hydrogen, made by mixing in a retort 4 parts of oil of vitriol with one part of alcohol, and applying a gentle heat. The plate should be held over this mixture for a period ranging from five minutes to half an hour. You may

observe the progress by the light of a candle, screened by yellow glass or paper.

Phosphuretted and sulphuretted hydrogen (for the process of making which see chapter on chemicals) I employ in a similar manner, only the exposure need not be so long.

11. The final fixing and finish is given to these pictures as follows:—

Dissolve in 1 quart of water,

15 grs. chloride of zinc,
30 grs. hyposulphite of gold,
20 grs. sulphate of soda,
1 oz. sulphuric acid, pure.

Immerse the picture for a few minutes, or until a slight change is apparent. Then rinse the picture, dry, and rub it with a buckskin buff. A little sweet oil will heighten the polish. If you wish a dead surface, you have only to observe extreme cleanliness in the whole process, and omit the final polish.

II.—The Formula Explained.

1. The first preparation of the plate has for its object the production of a peculiar molecular arrangement in the particles composing the surface. On this one thing—molecular arrangement—the whole phenomenon of colouration depends. Those who work the process are urged to keep in view the fact that this preliminary method greatly conduces to the final result.

2. The "Singular Compound," described above, I will not attempt to explain chemically. I will simply urge the absolute necessity of a strict adherence to the formula, both as regards manipulating and the character of the chemicals. Lengthy as the process may seem, it is very simple.

3. The action of heat and of red light, in modifying the surface is, I think, to disintegrate the coating, and to give it a different structure. The result is an increase of sensitiveness, and this alone would seem to account for the superiority of the results as to strength and brilliancy, and for the more certain reproduction of yellow and green.

4. The quickening agents I have named may be greatly varied. The object of their use is to aid in reducing the silver compound formed to that condition at which colours are formed. It is difficult to tell what the compound on the plate is, but it is a peculiar compound of silver. Anything that will tend to reduce this salt to the state, or to the point where colour forms, will quicken the process. Aldehide (sic) is one of the substances which deserve a thorough trial.

5. The action of the developers may be explained in a similar manner. I do not suppose that they produce colour, but that they continue the molecular transformation of the surface commenced by the coloured rays.

6. The fixing agent acts by way of deoxydising the chemical surface. It also effects a partial decomposition of the surface, and those combined chemical agents, such as chlorine, fluorine, etc., which would otherwise react upon the picture and destroy. All the pictures which I have treated thoroughly have remained fadeless. Those which have been carelessly done have faded very much, and some of them have deteriorated in darkness

There is, no doubt, some buncombe in the formula, and it is, to me at any rate, a great disappointment that Hill did not state the final composition of his "Singular Compound." That there is great similarity in many of the steps of his process and those used by Becquerel and others is apparent to all familiar with the same, and possibly some of his volatile gases and essences are but put in to make the process appear more scientific. When it comes to his ambrotype methods and printing on velvet and other fabrics he is sane enough, and they differ not at all from ordinary practice.

NEW BLEACH FORMULÆ FOR THE IVES MORDANT DYE-TONING PROCESS.

[Mr. F. E. Ives, who for some time past has been engaged in developing the chemical procedure in colour toning by the bleach mordanting dye process, sends us the following communication describing modifications in the formula for the bleach. In the issues of the "Colour Photography" Supplement for January, 1919, p. 1, June 4, 1920, p. 24, and November 5, 1920, p. 43, will be found notes on the successive stages through which the process has passed to its present formula.—Eds. "Colour Photography" Supplement.]

Heretofore I have recommended bleaching baths containing either equal parts of potassium ferricyanide and chromic acid or a still larger percentage of chromic acid.

I find that, beyond a certain point, the advantage gained by increasing the percentage of chromic acid is due to the increased acidity of the bath, and other acids may therefore be in part substituted for chromic acid.

A bath containing a greatly reduced percentage of chromic acid can, by the cautious addition of sulphuric acid, be brought to duplicate the action of baths made by my older formulæ.

This discovery pointed the way to overcoming the only weak points in the process, which were: (1) A teadency so to harden the image in the shadows of an over-dense positive that it would resist the absorption of dye; and (2) the necessity for considerable washing between the bleaching bath and the dye bath, which, if carelessly done or overdone, was apt to make uneven or relatively weak dye images.

With the following bleaching bath and sufficient acetic acid in the dye baths, much denser positives can be successfully converted to pure dye images, and only a thorough rinsing of the bleached print is necessary before transferring to the dyo bath:—

Water	30 ozs.
Potassium ferricyanide	20 grs.
Chromic acid	5 ,,
Acetic acid, glacial	1½ ozs.

It was also obvious that another oxidiser might very probably be successfully substituted for chromic acid, and as the result of further experiment I am now using the following formula:—

Water	30 ozs.
Potassium ferricyanide	20 grs.
Ammonium bichromate	10 ,,
Acetic acid, glacial	1½ ozs.

If the yellow stain is thoroughly washed out of the high-lights after bleaching and before dyeing, much less washing is required to clear the high-lights after dyeing, but if this procedure is preferred the washing before dyeing should be done in slightly acidulated water to secure against the production of uneven or relatively weak dye images.

F. E. Ives.

LOUIS DUCOS DU HAURON.

THE following German appreciation of the founder of processes of three-colour photography is published as a translation from "Photographische Industrie," by "Photo-Era":—

Although Eder in his "History of Photography" points out expressly that the foundations of the theory of colour-photography were laid entirely by a single person, namely, the Frenchman, Louis Arthur Ducos du Hauron, nevertheless the name of this extremely meritorious investigator is but little known in outside circles. The greater part of the various colour-processes are always known under the names of other men, and yet Ducos du Hauron, over whose work an unlucky star seemed to shine from the beginning, was the first to mention this particular process. Only one year afterward, no less a person than the clerk Maxwell took hold of the problem of colour-photography, and as one may readily suppose, without knowing anything of his investigations, the twenty-five-year-old Ducos du Hauron, on July 14, 1862, sent to his friend L. Lélut, of the French Academy of Sciences, a treatise with the request to lay it before the Academy. This treatise, in its fundamental features, contained the additive process for producing in colours photographs, projections and individual views—in short, the whole process as it was brought into practice in the nineties of the last century by Ives and Miethe with the aid of the then recently developed photo-chemistry. Even the half-pervious mirror was not omitted, by means of which two diaposi tives, placed together at an angle of ninety degrees, could be examined in the viewing-apparatus. That the idea of coloured pictures viewed simultaneously with stereoscopic effect was also mentioned, shows that Ducos du Hauron allowed nothing to pass without observation in order to follow up the problem to its last offshoot. He was not satisfied, however, with the one solution, but also mentioned (and here he stands without a forerunner) colour-photography by means of a screen, such as Joly and Lumière later constructed. Lélut gave the treatise to one of his colleagues outside the circle of the Academy, who rejected it with absolute lack of comprehension. Who it was that gave this unfavourable decision we cannot know to-day. In his valuable book, "La Triplice Photographique des Couleurs et l'Imprimerie," in 1897, Ducos du Hauron himself speaks of an anonymous colleague. It said that the deductions were not sufficiently strong, the conclusions were altogether too audacious—"hasardée" it was called—its practicability appeared doubtful! That upon this death-sentence of the expert, Lélut advised his young friend to withdraw the treatise, cannot be wondered at. Another series of works, in the year 1869, in which Ducos du Hauron treated subtractive colour-photography, and in which he came into competition with Ch. Cros, was also unable to obtain the attention it deserved in wider circles. When he had an opportunity to exhibit a few simple proofs to the French Photographic Society, the colour-sensitive plates were lacking, without which colour-photography could not possess a living existence.

Ducos du Hauron laboured tirelessly with his brother Alcide in the further development of colour-photography, and in 1878 he was able to say that every photographic process could be utilised in three-colour printing. In order to spare him the bitterest pangs of poverty in the evening of life, the French Government granted him a niggardly pension of twelve hundred francs a year, and the Vienna Photographic Society in the year 1904 raised for him an honorary gift in the interested circles of technical photo-mechanical printing.

Still less attention than the colour-photographic work of Ducos du Hauron received, was given to another proposition of his—made in the year 1864—by which he stands at the head of the development of the cinematograph. He received at that time a French patent for a photographic camera for producing consecutive pictures. This apparatus, which presumably could not have been completed, was to have had the following arrangement: There were, side by side, two sets of sixteen similar lenses, each set joined in four horizontal rows. On the light-sensitive plate, therefore, there were thirty-two fields of exposure. The exposure, made by means of a cloth-roll, begins in the first set in the upper row, passing to and fro to the inner field of the lowest row; from here it springs to the adjoining field of the second set and ends in the upper inner row again. In this Ducos du Hauron had just as little success, which was also denied to his countryman Dumont, who in 1861 tried to make pictures with a single lens on plates arranged consecutively on a band and changed rapidly. Here, also, it must be conceded that he was the pacemaker of a technique that has now become very important.

News and Notes.

HYPERSENSITISING AUTOCHROME PLATES.—In a short note, published in the current "Bulletin" of the French Photographic Society, M. Jové gives some particulars of his recent experience in hypersensitising Autochrome plates. In pre-war days it had been his custom to use for this purpose the hypersensitising solution prepared and sold by MM. Poulenc, which, up to the year 1914, yielded most satisfactory results. But now the same preparation, when employed with Autochrome plates of recent manufacture, is found to be unsatisfactory, a failure which M. Jové ascribes to improvements in the panchromatic quality of the Autochrome emulsion. As it appeared that the present-day plates are not susceptible to the hypersensitising formula which previously worked well with them, M. Jové has fallen back upon the method of hypersensitising worked out and described by M. Ch. Simmen ("Bulletin Société Francaise de Photographie," 1910, p. 275; "Colour Photography" Supplement, September 2, 1910, p. 66). By adjusting the formula, as directed by M. Simmen, the quality of added colour-sensitiveness can be varied according to requirements. The basis of such adjustment is that pinachrome sensitises for the yellow; pinaverdol, for the green, and pinacyanol for the red. At a recent meeting of the French Photographic Society M. Jové showed a series of comparative Autochrome transparencies in demonstration of the effective use which can be made of hypersensitising.

COLOUR CINEMATOGRAPHY.—Brief particulars are given in the "Patents Journal" of the specification (not yet accepted) of C. Parolini and G. Perron for a process of cinematography in natural colours. To obtain a film for projecting in colours, a negative is taken with an ordinary camera but used sideways so that the film is moved horizontally. A rotating orange and green filter is used so as to obtain successive pairs of images A . . A^1, B . . B^1, etc., Fig. 1, and the film is fed as shown in Fig. 6. The negative 1, Fig. 3, moves at right angles to the positive 2, the feed mechanisms being appropriately adjusted for the necessary film movements and connected by an endless chain 19. The positive film is projected in an ordinary projector fitted with two coupled objectives 25, 26, Fig. 7, which are provided with corresponding green and orange filters and are adjusted by a micrometer screw 29 so as to superpose the images on the screen. If the negative has to be taken at a greater speed, say three times the ordinary speed, the camera is fitted with a rotating at double the ordinary speed. The negative is reproduced in such a way that the successive pictures are reproduced in pairs side by side as screen having an orange, a red and an opaque sector so that blank spaces A, Fig. 2, occur on the negative film between the pairs of images A . . A^1, B . . B^1, etc. In copying the negative the intermittent displacement of the film is correspondingly increased.

SPOTTING AND TAKING OUT DEFECTS FROM SCREEN-PLATE COLOUR TRANSPARENCIES.

The films of all screen-plate colour transparencies are very delicate, particularly the Autochrome, which calls for very careful handling. Many of the colour pictures that I have seen bear witness to the fact that this essential was not fully realised by the photographer, for not only do spots, pinholes, and other defects manifest themselves, but many workers quite fail to take them out in a satisfactory manner, or ignore their presence altogether. Nothing tends to detract so much from the beauty of a colour transparency than defects of the kind mentioned, and it is, to my mind, more important that they should be avoided, or at least touched out even than is the case in ordinary photographic work.

I must first point out that the taking out of defects in a screen-plate colour transparency must be adapted to suit the character of the image formed upon the plate; and, except under the most favourable conditions, involves some risk of making the last state of the transparency worse than the first. The photographer has therefore, on account of the peculiar delicacy of the plate, to make his choice of leaving the defect alone, or of risking the total spoliation of the plate; but it should be added that this is not very likely if the work is approached carefully and in a commonsense way. It cannot be too strongly emphasised however, that the photographer must keep carefully before him how very delicate and easily injured the surface of an Autochrome plate really is, when compared with what an ordinary plate will permit in the way of wrong treatment without harm resulting. Further, even the simplest spotting, no matter how carefully done, will still be visible on the finished picture; and a bad defect, no matter how skilfully treated, is almost impossible to eliminate entirely. From this it will be seen how important it is to *prevent* the possibility of such making their appearance, by careful, systematic methods of working, and by an implicit following of instructions.

One of the commonest defects met with among Autochromes is the green spots of various sizes, caused by the abrasion of the film, the varnish coating allowing moisture to penetrate the screen. The effect of water, or even moisture, upon the more soluble dyes composing the screen is very rapid; and I have known a plate taken from its final brief washing, after the film has been lightly scratched, which developed a circle of intense green as the drying was in progress. It is quite possible for the film to be broken, and no harm result unless the varnish protecting the screen becomes perforated as well, allowing the admission of moisture. These green spots are troublesome defects to get rid of, as they are often of quite a large size; and, by reason of their intensity, ordinary spotting is of very little use at all. There are two or three suggested methods of minimising these defects, though I have yet to find one that is satisfactory, and not easily detected. The late Mr. McIntosh recommended that the spot be clean cut out—a job that I must confess that I have never yet succeeded in doing very successfully. A lantern, or other slow plate of the same size as the transparency is exposed behind the latter for a very brief period; developed in the ordinary way to obtain a faint grey image; and fixed and washed in the usual way. The spot is then worked up with transparent water colours, and registered with the Autochrome, serving it for a cover glass. It must be kept in mind that it is difficult to "match" with hand work a chemical image. This applies more to colour transparencies by the screen-plate methods than to ordinary methods of working up.

We now come to consider the taking out of defects caused by the damaging of the photographic film, without the screen being injured or discoloured. It is sometimes possible to repair a scratch or vacant place in the picture by fixing upon it another piece of film of the same colour taken from another spoilt plate. This latter is cut out very carefully with the point of a sharp pen-knife or an old safety-razor blade, keeping to the shape of the original defect as closely as possible. This latter is then given a fine coat of clear gum, the piece of new film gently coaxed into position and allowed to dry; after which any irregularities may be very much minimised by careful working up with suitable transparent water colours. The majority of beginners make the mistake of using too large a brush; most of my own work is done with a No. 2 sable. The colours should be used very dilute, for it is better to secure additional density by means of two or more applications than to risk matters by over much hurry or by the application of too much colour at once. It should be kept in mind that these colours are really stain; and, once applied, are not removable like ordinary colours, even if the film of the plate would stand such treatment. No attempt must be made to wipe off the colour if too much has been applied, for such would only injure the film. If any difficulty is found in making the colour "bite" on the smooth surface of the film the brush should be moistened with a little clear, thin gum water prior to taking up the colour. All spoiled Autochromes should be saved, for they are most useful for testing the effect and correcting the density of an application of colour before

experimenting upon a valuable transparency. If, however, an Autochrome is not available, an old negative may be employed for testing colours.

We now come to consider the spotting-out of simple defects such as pinholes; and there are very few plates indeed that do not call for some attention in this respect, no matter how careful the photographer may be. It is most important that, even for simple spotting, the transparent water-colours be used, and not the ordinary artists' tale colours, since these are quite opaque and useless for the purpose. I have seen many colour transparencies which were completely spoilt by these being used. Though almost all plates require a little spotting, it is a mistake to run the risk of overdong this. The screen of an Autochrome plate itself will often allow small pinholes to be almost invisible, especially when they come against the sky or other brightly lighted part of the composition. In colour work, in common with other forms of photographic spotting, it is far easier to take out or render less evident defects in the darker parts of the subjects than when these appear against a light portion. When spotting an Autochrome plate the beginner often works with his eye too close to the transparency, and then obtains a false sense of the amount of colour needed to make the defect invisible. The larger the transparency the farther it is held from the eyes in the case of a person of normal vision, and a minute touch of the *right* colour may have the effect of hiding an ordinary pinhole far more effectively than would a much deeper application. Too little care is often taken in adjusting the *depth* of colour to suit the surrounding area; and in the proper observation of these details will be found the secret of success in spotting colour plates. The actual spotting differs in no way from that employed on negatives and prints. A small pinhole should be completely blocked out with one touch with the point of a nearly dry brush, while a larger defect may be considerably modified with several touches. The idea is to fill out the defect with just enough harmonising colour of the same transparency; this grasped, there is little to add. Of course, no attempt must be made to alter existing colours or effects. Such may seem possible in theory, but, apart from being quite illegitimate, are unsuccessful in practice.

So far, I have mentioned the Autochrome process mainly, though much that has been written applies also to the Paget process, though I must say in my own experience spotting is less frequently necessary with this method, since the films of both negative and transparency plates are much harder; and, provided reasonable care is taken, the negative, or positive, should require little or no spotting. When this is required, however, great care must be taken not to carry things too far in the matter of spotting, by reason of the fact that a Paget colour picture is much more transparent than an Autochrome. Also, very careful mixing of the colours is essential, or the result will be that the pin-hole shows as a spot of intense colour. My own plan, when a Paget colour transparency requires spotting, is to attebpt to do this on the negative, so that none whatever will be needed upon the transparency; and if this is done carefully, it will not he found a very difficult matter. As with Autochromes, the transparent colours must be used, for the additional reason that if the ordinary opaque artists' water-colours are used their somewhat gritty composition is almost certain to scratch either the viewing screen or the transparency when registering. This trouble need not be anticipated with the transparent colours, though the two plates should not be moved about upon each other more than is necessary, or the slight irregularity created upon the film by spotting may cause scratches upon the surface of the viewing screen. It will be found best to register the transparency prior to spotting, so as to gather some idea of the tint required; the two plates being clipped together while the colours are mixed and their effect tried upon a spoilt plate. The two may then be separated, any grit or dust removed, and the spotting done. Care must be taken to see that the colour is thoroughly dry before re-registering. During this stage the photographer must be careful to avoid removing the spotting by the friction between the glass; the movement should be very gently done, or scratches to one or other of the surfaces may result. So far I have only mentioned the spotting of the transparency plate, but it sometimes happens that a tiny pin-hole in the viewing screen may be profitably filled in with a spot of colour. It is only fair to add that this should be very gently done.

I believe that few workers varnish their Autochromes other than those required for lantern projection, owing to the difficulty that beginners always experience in getting an even application of the varnish. There is really no need to varnish colour transparencies, from the point of view of protecting them, though varnishing will protect any spotting during the fixing of the cover glass and binding up the picture. Paget colour transparencies should not be varnished, as the interposition of even such a thin film between the plates would tend to prevent the perfect contact between them upon which depends the production of a perfect colour result.

ROBERT M. FANSTONE.

COLOUR TRANSPARENCIES AT THE NORTHERN EXHIBITION.

THE room at the Northern in which the colour transparencies are shown is of considerable size, and so has allowed of the exhibits being displayed in frames round the walls. At very few exhibitions have transparencies been arranged with such a degree of comfort to the visitor examining them. The illumination is by light directly transmitted through the transparencies; apparently it is of a slightly yellowish tint, no doubt of advantage to transparencies which err in the direction of coldness of rendering, although we can imagine that some exhibitors will be inclined to criticise its effect upon nuances of colour. However, a scheme of illumination which is uniformly satisfactory as regards showing to the best advantage each single transparency in a miscellaneous collection has yet to be devised. Generally speaking, the exhibitors have no fault to find, but every reason to be satisfied, with the arrangements made at Liverpool. And it must not be forgotten that the collection is a large one, including 282 separate transparencies. The compilers of the catalogue may, however, be criticised in respect to the heading describing the colour section, viz., "Natural Colour Lantern Slides." Most of the exhibits are by the Autochrome process, but they are not all lantern slides.

Some exceedingly fine work, including that by notable exhibitors, is shown. H. C. Messer has a most pleasing picture of a quiet English village street (409), the atmosphere of which is well rendered. We do not like so well Mr. Messer's 401 and 410, which appear too green, but his 400 has just the right quality of mellow colour. In 405, by A. Reid, the colour is hard, but 408, by the same worker, is an excellent version of the colour in rhododendrons. D. Mischol shows a beautiful autumn scene (412), in which the distance is contrasted with a vivid sunlit foreground.

R. G. W. Bush has a fine piece of work in No. 384, but the predominance of viridian in No. 387 is wholly untrue and unpleasing. No. 388, however, by the same worker, is a much better rendering of greens. N. E. Luboshez shows his technical triumph in the shape of the Autochrome of a soap bubble enclosed in a glass case (392). Louis J. Steele's two nude studies (Nos. 372 and 375) are probably the best things yet accomplished in this field of work; in 372 the flesh tones in sunshine are particularly well done.

Henry Irving's work is in the sphere of Nature photography, in which Mr. Irving has practised with such great success for many years. No. 377 is a set of birds' eggs in strong relief and most faithfully rendered. No. 325, which receives a plaque, is a remarkably colour-correct rendering of apples; it is a technical exercise pure and simple.

Another transparency (363), by R. G. W. Bush, is an extremely fine rendering of a flood of sunshine taken against the source. More work of this description should be attempted by makers of colour transparencies. Miss Gladys Openshaw has an excellent rendering of nasturtiums in No. 349, and of iris in No. 350a. Among the landscapes a special note must be made of the open view with cumulus clouds (336), by J. C. Warburg, which very strongly con-

vays the feeling of open air. No. 339, by the same worker, has this quality in lesser degree.

Snowscapes being rarely attempted subjects in colour photography, G. S. Sansom deserves special commendation for his transparency (313), which has the true iridescence of snow, and is entirely successful. R. M. Fanstone has two studies, both charming in colour (306 and 307), but No. 285, by the same exhibitor, has the rather unpleasant viridian hue, which appears to be a somewhat prevailing defect. A fruit study (247), by A. Walburn, is exceedingly fine colour, and the pair of transparencies (243 and 244) by R. Rigby deserve a mention for their artistic colour selection. F. G. Tutton is another worker who, in No. 235, scores a high measure of success in a study of strong sunshine. Still life and flowers form the subjects of a fairly large proportion of the exhibits, and among these must be mentioned No. 192 by P. R. T. Garnett, Nos. 169, 175 and 179 by A. Benson Ray, and No. 162 by W. Scruton.

THE HILLOTYPE PROCESS OF COLOUR PHOTOGRAPHY.

To the Editors.

Gentlemen,—The reason why Mr. Wall and many others have looked upon Hillotype as being one of the colour photography swindles of the past is because of the way writers of the period looked askance at and described the claims of Mr. Hill. This early experimenter appears not to have had a fair hearing, and our thanks are due to Mr. Wall for putting us wise, and to yourselves for publishing his article in the "B. J." Colour Supplement dated January 7.

Modern writers on photographic history have apparently taken their cue from the old and slighting reports of the early writers, for the "Cyclopædia" (not "Encyclopædia"), published by Cassell's, is not the only work of reference that speaks depreciatorily of Mr. Hill's work; the reference named is, in fact, very kind in comparison with others.

A volume to which most people go for their historical facts is Harrison's "History of Photography" (1888), and the comments concerning Hillotype are particularly severe. The writer, under the heading of "Pretended Discoveries of Photography in Colours" (page 122), deals with deliberate frauds, and goes on to say: "In 1851 an American preacher named Hill obtained almost general credence for his statement that he could produce photographs 'glowing with all the colours of Nature!' Naturally, so wonderful a process was to be called Hillotype. The Rev. Mr. Hill obtained a considerable sum of money by inducing photographers generally to subscribe—payment in advance, of course—for a book which should contain all the details of this startling discovery. After many delays the promised book appeared; but what was the disappointment of the subscribers to find it a mere twopenny pamphlet containing the outlines of the Daguerreotype process, with complications and additions just sufficient to render the obtaining of any picture at all a very important matter." The "octavo volume of 175 pages" in the possession of Mr. Wall, and dated 1856, may be the one the writer of the "History" refers to, or it may be a later edition, enlarged and illustrated.

I always look upon John Werge as having been the best and most reliable chronicler of American photographic affairs of half a century or more ago, for the simple reason that Werge left England in March, 1860, to open a studio in New York, and while there made the acquaintance of most of the early American workers. Werge, however, tells us very little about Hill. Writing of Messrs. Gurney and Sons' studio in New York, he says: "This house was the oldest in connection with photography. Mr. Gurney, senr., was one of the most eminent 'professors' of the Daguerreotype process, and was one of the committee appointed to wait upon the Rev. Wm. Hill, a preacher in the Catskills, to negotiate with the reverend gentleman (?) for his vaunted secret of photography in natural colours." That is all. The house of Gurney in later years boomed a Hallotype (not Hillotype) process, which appears to have been based upon "the application of Canada balsam" in some way, possibly a kind of crystoleum process. Werge's remarks may be found in his "Evolution of Photography" ((1890), page 71.

I have before me a pile of photographic instruction and reference books bearing dates between 1851 and 1870, and there are several brief references to Hill's work in them, but not a single one of them is complimentary, but rather the reverse. The best attempt to describe Hill's experiments is made by W. Sparling in his "Theory and Practice of the Photographic Art" (1856). Says the author:—"Mr. Hill had undertaken a series of experiments . . . . but for a long time with little prospect of success; but in one of his experiments certain phenomena presented themselves which greatly surprised him. . . . . One colour—red—in the figure of a vestment, developed itself in the most brilliant ruby colour; he repeated his experiment many times, but without meeting again the same result. . . . . Believing, however, that in certain circumstances the latent colour of the image was present, he proceeded with his experiments, and found that the vapour arising from many metals, such as arsenic, cadmium, zinc, selenium, bismuth, potassium and sodium, possessed the power of developing latent images with their lights and shades. The same result was obtained with different gases. . . . . In January, 1851, he obtained forty-five designs, which presented all the different colours and with perfect gradations. Mr. Hill has not described his process further than that it neither resembles that of Daguerre nor Becquerel."

Mr. Sparling's comments were written in the year of the appearance of Mr. Hill's book, but no copy of the volume appears to have reached this country. Mr. Sparling probably gleaned the details he gave from the periodical and scrappy reports of the discovery which came from America.—Yours faithfully,

L. Tennant Woods.

THREE-COLOUR AND DIRECT HELIOCHROMY.

To the Editors.

Gentlemen,—After reading Mr. Wall's paper in the January "Supplement," some of your readers may be wondering why he should take the trouble to send such a long letter such a long way, regarding it as of only antiquarian interest. But it is much more than that.

Some years ago I was assisting at a demonstration of a three-colour process (it doesn't matter which). Mr. Wall was standing beside me while I went through the usual conjuring these processes require to get a decent result.

Turning to me he asked pointedly, "Do you really believe in the future of colour photography?" He could see I hesitated, having still a sneaking regard for truth, so he added, with emphasis, "Because I *do*."

It struck me forcibly that afternoon, as the little crowd watched my movements, that though they were so eager, and inquisitive about colour photography, he alone had expressed a living faith in it.

This "Hillotype" Mr. Wall describes is evidently one of the very earliest attempts to obtain colour by the direct method. I think a search among the records of later French or German experimenters might produce more definite instructions. At any rate, we know they obtained "something," and he also has got "something," and in thanking him for his paper, we should be still more grateful if he would send us over some of his results to examine.

Poitevin and his successors spent a lot of time endeavouring to add colour to their positives, and claimed to get some fair results. They only dropped it when the indirect "three-colour" method arose because in that there seemed to be "money right away."

Now that we have seen what three-colour can do (and it serves for some things), it seems time we turned leisurely back to the work of these early experimenters. Physical science has been almost revolutionised since those days, and it seems reasonable to suppose we should soon improve on their efforts. Every photographer should be dissatisfied with his art, even if he looks on it only as a means of earning a more or less honest living. If he thinks, he must see

it as an art that has struck half-way. Every time he looks on the focussing screen he sees two things, viz., form and colour—every time he develops a negative he has but one form. Until this other half has been captured, satisfaction with the art is incomplete, because in the "colour" half lies the greater proportion of life and beauty.—Yours truly,

S. G. YERBURY.

35, Fairholme Road, Baron's Court, W.14.

News and Notes.

GRAIN COLOUR SCREEN PLATE.—A patent specification, No. 152,002 (open to inspection, but not yet accepted), by P. Faulstich, describes methods for producing multi-colour grain screens in which the colours are produced partly by spraying a base with coloured dyes and partly by immersing the film in other dye baths. The immersion treatment may affect the parts already coloured by spraying or the sprayed colours may be utilised as a resist and subsequent to immersion in another coloured bath be washed away, and all the colours produced by such successive treatments.

AUTOCHROMES OF SANDRINGHAM.—A supplement to the "Illustrated London News" of January 8 last contains two reproductions of Autochromes of York Cottage, Sandringham, which are part of a much larger number recently taken by Messrs. J. Russell & Sons. Messrs. Russell, as is perhaps well known, have given the Autochrome process a prominent place in their business for a long time past. The present series of Autochromes taken at Sandringham were carried out by Mr. Stoneman of that firm, whose work received very cordial interest and appreciation on the part of H.M. Queen Mary.

THE UVACHROME PROCESS.—In "Photographische Korrespondenz" for December last a somewhat flowery report appears of a lecture delivered in Vienna on the Uvachrome process of colour photography devised by Dr. A. Traube, and at present in process of introduction to the Continental public. From the remarks of the lecturer it is evident that Uvachrome is a variation of the process of making and printing three-colour sensation negatives on the simplified lines which Mr. F. E. Ives originated a few years ago in his Hi-block. But the lecturer dealt in generalities, and apparently said so little on the essential technique of the process that the editor of "Photographische Korrespondenz" appends a brief description, derived from the English patent specification, which was published in this Supplement in November last.

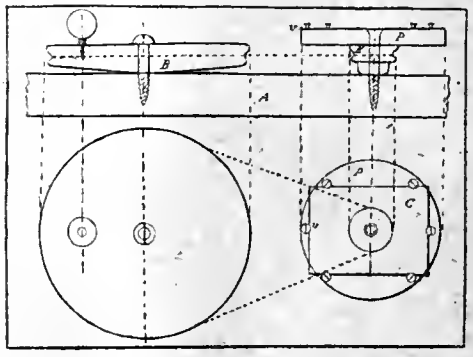
AUTOCHROME DEVELOPMENT.—In a recent issue of "Photo-Revue" M. M. R. Espitallier writes of his satisfaction with diamidophenol for Autochrome work, both as a developer in the first instance, and also for re-development. The adoption of the developer for this latter purpose was the means, in his experience, of avoiding frilling of the film. M. Espitallier works as follows:—A red light is used in the dark room, and is covered for the first minute or two whilst the plate is immersed in a desensitising bath consisting of

Potass bromide	1 gm.
Soda bisulphite lye	2 c.c.s.
Water	100 c.c.s.

At the end of about two minutes the plate may be exposed to red light; it is rinsed for an instant, and then developed in the ordinary diamidophenol solution made up according to the Lumière formula. Development is stopped at the point when the negative image, which in the initial stage shows very plainly by transmitted light, begins to disappear. The plate is then again rinsed, reversed in a bath of acid permanganate or bichromate, and re-development carried out with the same diamidophenol solution. M. Espitallier finds this process simple, practical, and economical.

A COLOUR CAMERA.—According to an American cinematograph journal, "Shadowland," a new process has just been announced by Hiram C. Deeks, of Sea Cliff, L.I., who claims, with the aid of a new pigment discovered by him, to have evolved a process of colour photography in a practicable and workable form. Mr. Deeks has devoted several years to investigation and development work in this interesting field. Following the three-colour-separation theory, which involves taking three separate negatives of the image through colour screens, Mr. Deeks conceived it possible to take them in rapid succession upon different sections of a single plate. To this end he built several cameras and finally perfected an instrument which, it is claimed, meets all requirements by being rapid enough to take the complete exposure in a fraction of a second; absolutely automatic and precise so that the three separations were correctly balanced, and simple, making it possible for it to be operated like an ordinary camera, *i.e.*, by setting the time of exposure, winding and pressing the button. Mr. Deeks next turned his attention to the chemistry of colour, and later announced a colouring matter which had the peculiar qualities necessary to make the final step of the process possible. Several other, but less important, difficulties had to be overcome before Mr. Deeks obtained results which he was willing to show.

A WHIRLER FOR AUTOCHROME PLATES.—A correspondent of the "Photo-Revue" describes the following simple construction of a whirler for the rapid drying of Autochrome plates:—On any convenient solid base A a grooved wheel B is pivoted, and is provided with a small handle for rotation. A pulley E is likewise pivoted on the base, and carries the platform P to hold the plates. The two pulleys are connected by means of an endless length of twine, which



is wetted at the time of use, as it then grips better. The plates are kept in position on the platform P by means of six flat-headed screws, inserted in positions so as to hold the plates at points near to their corners. Of these screws, five are fixtures; the sixth *v* is removable, and allows of the plates being slid into position. Similarly, by removing it, they are readily withdrawn when dry. The pulley E being of small diameter relatively to the wheel B, a high rate of revolution is readily obtained.

STEREO-AUTOCHROMES WITH A HAND CAMERA.—At a recent meeting of the French Photographic Society, M. Ch. Adrien showed a camera of the folding pattern adapted for the making of stereoscopic Autochromes. A special lens-board carried the two short-focus lenses, mounted at a separation of 60 mm. M. Adrien arranged the baseboard in a position inclined below the horizontal in order to avoid cut-off when using lenses of this short focus. He fixed a wooden partition between the back frame of the camera and two slots in the lens front, and in this way was able to keep the front and back in the necessary position. Moreover, a groove in the front edge of the partition allowed of the latter being lengthened by utilising a black card folded on itself when employing the single components of the doublet lenses at twice the customary focal distance. M. Adrien showed his method of mounting the negatives (made on 9 × 12 cm. plates) so as to obtain a stereoscopic pair 8.5 × 17 cm. For this purpose a strip of 5 mm. width was cut from the upper or lower edge of the plate, and the two images then separated. Templates of card may be readily made for carrying out the cutting accurately, and when assembling the two separate negatives on glass, a strip of card of 5 mm. width is placed between the two, whilst two others of 25 mm. compensate for the difference of length. M. Adrien showed a fine collection of stereoscopic Autochromes taken with the camera which he had adapted in this way. At the same meeting M. Schitz mentioned the use which he had made of various light-filters during a single exposure of the Autochrome plate for the purpose of avoiding general blue-green predominant tint. In addition to the customary Autochrome light-filter, he employed during a variable fraction of the time of exposure a deep yellow screen and a red screen, *e.g.*, the Wratten G (yellow) and A (three-colour red). He employed the first for about 10 to 12 per cent. of the total time of exposure, and the second for about 5 to 8 per cent. of the time. The results obtained were excellent in all respects.

A SUGGESTION FOR A NEW METHOD OF PHOTOGRAPHY IN COLOUR

(A paper in the recently issued 1921 volume of "Penrose's Annual.")

The following method of obtaining a coloured photograph occurred to me about twelve years ago, but as I have never made any attempt to carry it out I can only put it forward for what it is worth.

Probably most readers of "Penrose's Annual" are aware that if two clean lenses are placed together there is at the point of contact a system of coloured rings which are known as "Newton's Rings." If the system is lighted by monochromatic light the rings are much more numerous than they are with white light; the size of the rings varies with the colour of the light. If O, fig. 1, is the point of contact, and

Fig. 1.

if rings are seen at A A', B B', C C', the distance apart of the surfaces at A, B and C respectively, will each differ from the other by half the wave length of the light used, i.e., if A is the first dark ring as seen by reflected light the distance apart at A is a half wave length, at B it will be a whole wave length, and at C a wave and a half. The rings themselves get closer together as they get larger, owing to the curvature of the surface. If, instead of two lenses, two plane surfaces are used, which meet along a line at O (fig. 2), the light and dark lines (still called Newton's rings) will be straight and parallel to the line of contact through O.

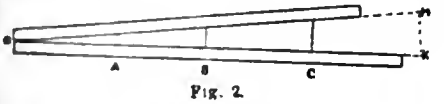

Fig. 2.

In this case the lines will be equidistant, i.e., O A, A B, B C, etc., and each is equal to $\frac{1}{2}\frac{OK}{HK}$ since, again, the distance apart of the surfaces increases by half a wave length from one line to the next.

A photograph of such a system of lines formed by monochromatic light could evidently be used as a diffraction grating. The distance apart of the lines formed depends upon the wave length, their number depends upon the purity of the light, for the light transmitted by a coloured glass or reflected by a coloured object, being a mixture of light of a great range of wave length, will only form a few (say, ten) lines, and will only form these close to the line M of contact O. The fringes are situated close to the surfaces producing them.

Suppose, now, that a film of celluloid could be formed consisting of a great number of tiny wedges as shown in fig. 3

Fig. 3.

at L M, M N, etc., each of which was just about wide enough to form ten lines, and this be placed in contact with a glass plate, then even with ordinary coloured light, fringes would be formed all along from L to Q. The distance apart of these fringes will depend, for a given angle of the wedges, upon the colour of the light used. By semi-silvering the lower surface of the celluloid film and the adjacent surface of the glass plate the fringes will be rendered much more distinct. If the film so mounted is pressed against the sensitised surface

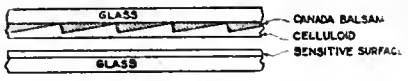

Fig. 4.

of a photographic plate, and coloured light is allowed to pass through it on to the plate, the latter will, on development, be made into a diffraction grating, of which the ruling is determined by the colour of the light. The plate can then be examined by slightly oblique light, and at a certain angle will appear coloured with the colour of the light used. Lastly, if such a film be placed in contact with the front surface of an orthochromatic plate, and the plate exposed in a camera in the ordinary way, a combined photograph and grating will be produced, which, printed and viewed at a certain angle,

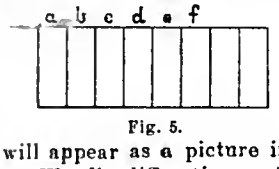

Fig. 5.

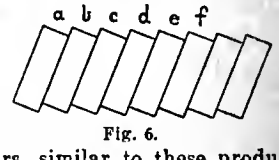

Fig. 6.

will appear as a picture in colours, similar to these produced by Wood's diffraction method. Provided, therefore, that the wedged film can be obtained, the production of coloured photographs by its means is perfectly simple; moreover, the photographs can be multiplied by printing in the ordinary way.

Several ways suggest themselves for the production of the wedged film. For instance, Wood described recently an "echelette" which he made by ruling a soft metal with a carborundum crystal, which gave him a series of parallel wedge-shaped grooves. A cast in celluloid of such a surface could be taken, the grooved surface of the celluloid semi-silvered, and then mounted, grooved side down, in Canada balsam on a sheet of glass previously semi-silvered, as shown in fig. 4. The thickness of the celluloid would probably not be enough to matter much (though this is, perhaps, the most doubtful point in the method). Instead of ruling the grooves in soft metal they might be made by clamping together a bundle of this glass or steel sheets *a*, *b*, c, *d*, *e*, *f*—each about one-thousandth of an inch thick (fig. 5). The upper and lower surfaces should be optically polished, and then the whole bundle inclined as in fig. 6. The celluloid cast could then be made as before.

REGINALD S. CLAY, D.Sc.

MONOCHROME, TWO-COLOUR OR THREE-COLOUR CINEMATOGRAPHY.

[In a recent Patent Specification, No. 154,150, of Zoechrome, Ltd., and T. P. Middleton, a process is described for the production of cinematograph negative film serving for monochrome positive films, and also for two-colour or three-colour positive films. The negative is taken at twice the usual rate, *i.e.*, at 32 pictures per second, and the section-exposures for monochrome film are alternated with those for the two or three colour-sensations. Composite colour positive films are printed from these latter. The following text of the specification describes variations of this system. Elimination of colour fringing is claimed to be one of the advantages of the process.—ED. "Colour Photography" Supplement.]

THE invention relates to that class of process for producing colour effects in cinematography in which each component picture of the film for projection is a miniature colour rendering of the subject, and does not rely on superimposition by means of filters in the projector to reproduce the colour effect on the screen.

The negatives for producing the films can be produced in various ways; but the invention relates to such negatives as are taken through one or more lenses successively through recurring colour filters.

Hitherto it has been found impossible in films for projection produced from such negatives to avoid "colour fringing," and one of the objects of this invention is to minimise this defect. Another object is to produce a negative film from which ordinary black and white films may be produced when required; and from which at the same time a colour film for projection may be prepared in such a manner that it can be exhibited through an ordinary projector at the usual speed, and interchangeable with black and white films without material alteration to the apparatus.

In short the invention consists principally in the production of a single negative cinematographic picture-film band, taken at the rate of 32 pictures per second, in which different colour elements alternate with the elements of an ordinary black and white film, and from which black and white and colour picture films can be produced that are susceptible of projection at the ordinary speed employed for exhibition of black and white pictures.

The normal negative taking speed of 16 pictures per second is increased to 32 pictures, and the colour filters are not consecutive but alternate with spaces which may or may not be filled with yellow or orange filters as usually employed in black and white photography in conjunction with a panchromatised base. Thus a negative, taken on panchromatised base, is obtained in which alternate pictures form elements from which an ordinary black and white film can be printed, while the remainder, being exposed through appropriate colour filters, form the component elements of a negative from which by subsequent printings a heliochrome can be prepared from a black and white positive.

When the negative pictures are combined by superimposition a colour film can be made which possesses the evenness of motion, sharpness and want of rainbow of a "hand-coloured" or "stencilled" black and white film, with the purity and detail of colour of a veritable heliochrome.

The negative is conveniently printed in the type of machine described in Patent Specification No. 16,353 of 1913. The machine therein described is, however, modified in detail to suit the aforesaid conditions. For example, the black and white film pictures must always be printed so as to close up the open order of the negative. The negative having been pulled down two pictures, one print is taken. Two picture shifts are made on the negative and one on the positive, and one further print is made; and so on. Thus a print is made which in all respects resembles an ordinary black and white film.

As, in colour films having colour images combined with black and white images, in order to further reduce the colour fringing, it is advisable to have the colour images slightly out of focus,

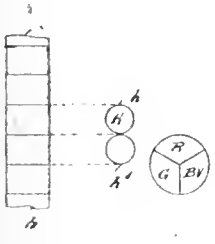

Fig. 1a.

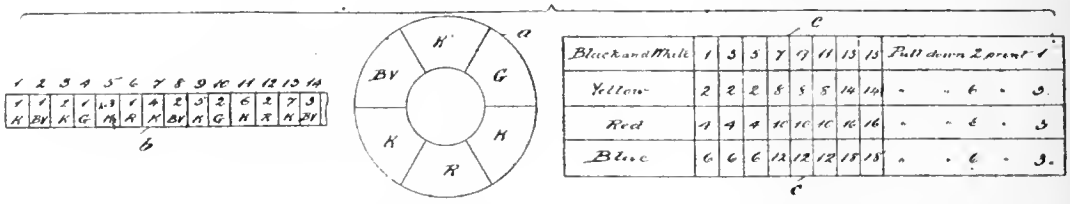

Fig. 1.

arrangements are preferably provided in the printing machine aforesaid for moving the lens and positive film in relation to the negative side.

This enables the want of sharpness of the colour images to be controlled. In addition, the less sharp methods of preparing colour images become available, and so the colours can be applied not only by recoatings of the black and white film, but also by the various methods of dye and colour transfer from gelatine reliefs. The colour images themselves can be transferred on to the black and white film by a suitable adhesive from a suitable support allowing transfer.

Whatever method of assembling the colour images be adopted the printing machine is discriminative and selects all the images of one colour from the single negative band, and as there must be as many images of each colour as there are black and white pictures it necessarily follows that in a three-colour process three separate images are printed from each colour element of the negative on to a black and white film; whereas in a two-colour process only two such impressions are necessary. Thus in a three-colour process on a black and white film the negative will, for printing the colour images, be pulled down six picture shifts, and three pusitive prints will be made; whereas in a two-colour process on a similar film only four picture shifts of the negative and two positive impressions will be necessary.

Three modifications of the process are shown in figs. 1, 2, and 3, in which *a* represents the colour screens, *b* the negative film, and *c* a development of the positive film presuming the use of one lens only. In these figures the numerals on the negative side and on the positive side represent the successive or consecutive motion phases. Figs. 1*a*, 2*a*, and 3*a* show the application of two lenses A A^1 and colour screens for the purpose of making negatives.

Referring now to fig. 1, or the former case, the negative *b* is taken through six screens.—Three yellow (K) such as are usually employed in black and white photography in conjunction with a panchromatised base, one blue-violet (B.V), one green (G), and one red (R), the yellow alternating with the other colours; whereas in the latter case, fig. 2, four screens would be used; two yellow (K), one red (R), and one green (G), the yellow alternating as before. These colours are only given by way of example, the yellow may be omitted altogether if desired; but it would then be advisable to substitute clear glass dummy filters of equal thickness for the colour screens.

Referring now to fig. 3. In certain cases, as where it is desirable to have very bright colours, the black and white positive film can be toned blue and thus form one of the colour elements. The negative *b* is then preferably taken through the four screens *a*, which consist of two red (R) alternating with blue-violet (B.V) and green (G) filters. Such a negative filter is not broadly new, but, in accordance with the invention, it is then printed, as in the case of the "two-colour or black and white film" already described; but the black and white film is toned blue in the manner well known to photographers. Such a film can be considered as being in technical parity with the others described, as the human eye is much less sensitive to blue than to either yellow or red, and thus a blue image appears dark and being sharp produces the desired optical effect on being projected. Advantage is taken of this in the well-known Sanger-Shepherd process, where a sharp blue is associated with two non-sharp dyed gelatine reliefs. The method of printing the positive film *c* in each of the above described methods is clearly shown in the respective developments of the positive film *c* in the diagrams, but, of course, out of step printing is to some extent possible.

For example, instead of the combination shown in the positive in fig. 3, it is equally possible to have the following combination:—

Blue, 1 3 5 7 9 11 and so on,
Yellow, 2 2 6 6 10 10 and so on,
Red, 4 4 8 8 12 12 and so on,

in which case the red is always in the middle as regards motion, the other individual exposures each picture being those immediately prior and subsequent to it, and these are alternately red and yellow, and yellow and red respectively.

In assembling the various colours on the black and white or toned film, care should be taken that the individual colour elements that constitute each composite unit of the complete film should as far as possible be those immediately prior and subsequent to the individual member of the base film.

Obviously coloured films prepared as above described are capable of being run through an ordinary projector at the ordinary speed, and, therefore, interchangeable with the common black and white film, thus obviating the use of special apparatus for the exhibition of the colour picture.

When using two lenses to make the negative film, one of the lenses may have a stationary colour screen associated with it, and the other may have rotatable screens, as indicated in figs. 1*a*, 2*a*, and 3*a*, the exposures being made alternately through the two lenses.

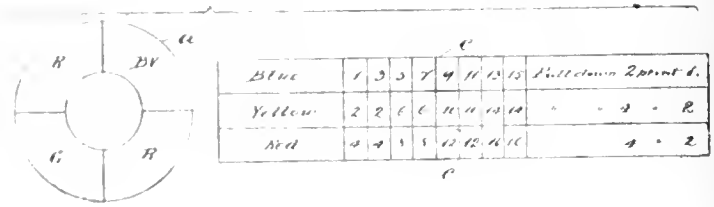

Fig. 3

THE AUTO COLOUR CAMERA.

By courtesy of Mr. F. Donisthorpe, 4a, Iliffe Yard, Crampton Street, Walworth, S.E., we have recently had an opportunity of seeing a camera for three-colour work which he is just putting upon the market under the name of "Auto." When one calls to mind the mechanical or optical complexity of cameras which have been designed for making the three colour-sensation negatives, Mr Donisthorpe's instrument appears as of extraordinary simplicity. It is, in fact, modelled upon the mechanism of the cinematograph camera, a simple cam movement serving to move the film into successive positions for exposure. Unperforated panchromatic film is employed, and the cam movement is such that the longer dimension of the picture is about 2¼ ins., whilst the shorter dimension is almost the width of the film. The three light-filters form part of the shutter mechanism, and are mounted in a vertical frame which operates, in conjunction with the film-winding cam, in the manner of a drop shutter. Thus, by means of a very simple outside adjustment, the three exposures can be made in very rapid succession, so rapidly that it is claimed for the camera that the three-colour-sensation exposures may be made within a total period of time short enough to allow of snapshots being taken. Also the shutter mechanism may be adjusted for giving time or bulb exposures. The sensitive film is obtainable either as a daylight loading spool or in lengths for loading of the camera in the darkroom. In the first form a spool for nine successive exposures, or rather sets of triple exposures, costs 2s. In the latter form, 1s. 6d. It will be understood that the apparatus is designed for the making of negatives from which three-colour prints or enlargements are prepared by the customary assemblage methods such as Raydex,

Pinatype, etc.; and the camera certainly represents a new and greatly simplified form of mechanism for this purpose. Its price complete with f/6 lens is £6 15s.

EXPOSING AUTOCHROME PLATES ON INTERIORS IN WINTER.

The exposure of an Autochrome colour plate indoors, under the weak light that obtains in winter, is a very different proposition to that of attempting the same work during the spring or summer. I have lately been conducting a number of experiments in this direction and—incidentally—wasting a number of precious and costly plates, ere I at last obtained really fine results.

First, as to the focussing. As the light is much less powerful far more care should be expended on this, otherwise, it is commonly found that some part of the plate is slightly "fuzzy," instead of absolutely sharp. Focus with the lens at full aperture and adjust until as much of the centre of the picture as possible is fully defined. Now work round the outside, constantly making small adjustments of the swing back and front until the whole is as definitely defined as can be accomplished. Patience expended in this way is amply repaid in the finished result, for it is really astonishing how much can be done to focus sharply by small adjustments, and the sharper the picture can be made—without stopping down—the greater the amount of light that passes and, consequently, the shorter the exposure necessary.

After the utmost has been done with the swing back and front, recourse must be had to stopping down the aperture of the lens, though this should on no account be done beyond the largest stop that will give accurate definition.

Colour rendering is not altered by stopping down considerably more than is actually needful, but the exposure is greatly lengthened, and it is difficult to develop fully the detail in the shadows without sacrificing the high-lights.

As an experiment on this point, I chose a dull, clouded day, and in an ordinary room, with large windows on one side facing west, focussed my camera. After obtaining the sharpest definition, I doubled the stop necessary to secure this, with the result that, on the ground-glass screen, the best lit and most prominent objects could only just be discerned on the glass. I then calculated my exposure and found it ran into some hours, so that I opened the slide and shutter, closed up the room and went away. When the time had elapsed I returned, closed the shutter and slide, and took it straight to the dark room and immediately developed. The finished picture gave me strong and vigorous rendering, but with less of the finer detail in the darker portions than another picture, taken under the same conditions, of the same subject, with a sufficiently small stop only to ensure good definition.

This leads one to the conclusion that the light is not only weaker, but lacks penetrative power, even when it is allowed to act for a proportionately longer time.

Calculating the correct exposure in winter, especially when the sky, as is usually the case, is overcast, cannot be judged by ordinary methods. The Autochrome plate, we are told, needs an exposure of 50 to 60 times that necessary for an ordinary plate, in order to obtain a fully exposed and correct rendering in colour of the object or scene photographed, but, in addition to this, we must add roughly six times the exposure needed when the sun is shining to compensate for the lack of penetrative power. Experience has convinced me that in winter, not only must we first obtain an approximately correct exposure, but that, whenever the sky is cloudy, it is essential to add five or six times the additional time needful under a clearer light. And, in addition to this, double or treble the whole. One cannot do more than hint on this point, for the speed of a lens varies so greatly, and the matter can only be correctly solved by making an experimental exposure or two for oneself. Controlled development must be followed to obtain an accurate result.

Temperatures, etc., vary so greatly at this season, with their accompanying result on chemical action that no other way is possible. One may have had absolutely correct exposure, but even then the plate may be spoiled if the automatic (2½ minutes) method is employed, because the development does not commence and is not carried on so vigorously as under warmer conditions. It is a good plan to have the dark room at a temperature of 60 degrees for working, and also to keep all solutions, etc., in a warm place, but be careful to test these with a thermometer when ready to use. My experience of the Autochrome is that it will not fog or frill readily under proper treatment, but too warm a temperature of the developer brings both these troubles at once.

Watch your development carefully by rapid examinations of the plate from a light fitted with Virida paper. Do not subject it to long exposure even to this; examine quickly and cover either the source of light or the tray containing the plate. It is a great temptation, where one can see the development, to carry this too far as more and more fine detail seems to be building up, but, if this is done, the resulting picture will be poor, washy, and thin in its rendering.

Remember that it is being examined by a very diminished light, and rapidly at that, and there is a great deal more detail there than can be recognised. Parts of the plate that seem to be only just faintly tinged with greyness in the developer will, after reversal and re-development, be found to contain vigorous and correct colour, while if this first development be prolonged to obtain more detail, we shall really be getting less in the finished picture.

Yet another hint, do not develop later in the day than can be helped, for the strongest light-action possible is required in reversal and second development to ensure the best result. In winter it is best to carry the plate in the tray, immediately it is immersed in the reversing solution, into the open air, so that the fullest and clearest light possible is utilised in the chemical action.

H. W. Canning Wright.

The Bleach-out Process.—Dr. G. Plotnikow, in a work, "Lehrbuch der Photochemie," a chapter of which is quoted in advance by "Photographische Industrie," makes the following observations on this much-investigated but now greatly neglected process of colour photography:—The lines along which the bleach-out process has hitherto been developed appear to give little promise of success. In the processes which have been brought forward the basis is the photo-chemical oxidation of dyes by the oxygen of the air or by other oxidising agents, such as hydrogen peroxide, organic peroxides, etc. The chemical process is therefore of the following type:

$$F+A=P$$

where F is the dye, A the sensitiser, and P the product which is obtained. A and P require to be colourless substances. In the case in question A is oxygen or some other oxidising agent, and F the light-sensitive substance. But inasmuch as oxygen is always present, that is to say, the substance A cannot be eliminated from the reaction, artificial means, the so-called fixing, require to be used in order to bring the reaction to an end. This fixing consists in reacting upon the dye with other substances which render it fast. Such reagents are, however, not easy to find, and new bodies produced by their action exhibit a difference of light absorption, so that there is an alteration of the appearance of the prints. It therefore appears that very little practical success is likely to come from the methods which have so far been recommended. There is, however, another form in which the process might be developed. The dye F could be one of a fast character in respect to oxidation, forming a colourless product in the presence of a colourless substance A. We then have conditions as follows:—After exposure had taken place the substance A would be removed by washing, evaporation or chemical decomposition. There would then remain only the light-fast dye F, and there is no reason to suppose that the colour-rendering would then be different from that originally produced. The difficulty of such a process consists in the discovery of suitable fast dyes of the required properties, and of corresponding compounds to react with them. It would be immaterial whether the reaction took the form of a synthesis, decomposition or other process. Inasmuch as this field has not been investigated, it cannot be said at the present time which dyes are adapted for the purpose. The organic chemist may be able to indicate them, and it is not impossible that quite new classes of dyes may come into existence which will provide the solution of the problem.

THREE-COLOUR LANTERN TRANSPARENCIES.

[With the introduction of the Autochrome and Paget processes the making of three-colour transparencies by the older assemblage processes has largely lost the interest, so far as practice is concerned, of colour workers. The practical details of these processes even tend to be forgotten; and therefore it is good to find two American workers, Messrs. C. K. Teamer and E. E. Miller, in the "Camera," doing the best thing to keep them alive, viz., describing their own practice in the making and printing of the three separate colour-sensation negatives. The following is a reprint of the chief portion of their paper.—EDS. "Colour Photography Supplement."]

THE apparatus required, taking it for granted that you have a plate camera, is not great. An anastigmat lens is a valuable asset, but, except for the most critical work, a long focus R. R. lens will answer, only the centre of the field being used. A single lens will not make a set of plates, the positives of which can be accurately superimposed.

The plate holders to be used should be carefully examined for accuracy, as the three plates made of the subject must lie in the same plane otherwise the images will not be exactly the same size. This, if it occurs in the red or blue printing plate, is very noticeable on projection. Also it is preferable that the holders be used as for vertical pictures, as there is less danger of moving the camera while changing slides.

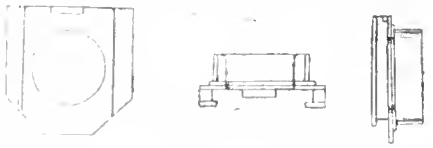
While any panchromatic plate will probably make a good set of separation negatives, we use and will give directions exclusively for Cramer's Spectrum Plates used with Cramer's Tri-colour Filters. Do not attempt to use the filters of one make on the plates of another, or *vice versa*, and then blame us or the plate maker for the poor results. "Adopt one brand of plate and stick to it," is very good advice that is often given and seldom heeded. The Cramer tri-colour filters, size 2 in. square, are at present $12.50 per set, which is the only expensive article required. Beside the filters the following will be required: Kodelon or some other make of paramidophenol hydrochloride, bichromate of potassium, alum, strong ammonia water. One ounce each of methylene blue, tartrazine and basic fuchsine. We will also require one dozen 8 by 10 Eastman positive film for printing the positives. The following are convenient, but not essential. Four 1,000 c.c. flasks (slant), three 800 c.c. beakers (tall pattern), two dozen wooden photo clothes pins or slips to be waterproofed in melted paraffin wax.

A filter holder will be needed, and can easily be made. Procure from the druggist a pill box slightly larger than the lens to be used. The lid is the part required. Glue to the top a two and one-half inch square of heavy card; when dry, cut a hole through both corresponding to the diameter of the lens, line the box with velvet till it is a snug fit on the front cell. On the two sides of the two and one-half inch card, glue strips about one-quarter inch wide and equal to the thickness of the filters and on top of these a slightly wider piece to form a track in which the filter freely slides. A small piece of card fastened at the bottom to keep the filters from dropping through, completes the holder. This is not elaborate, but answers the purpose. The sketches fully illustrate its construction.

It is always best to expose the plates through the filters in a certain rotation (red, green, blue is satisfactory), which, if always used, will avoid confusion.

We will assume that lantern slides are to be made, and give instructions accordingly.

For the first attempt a rather simple subject is suggested, a fruit group containing an orange, a banana, a red and a green apple. These can be placed on a coloured or plain dish, but one of white or containing too much white should be avoided. A suitable background should be used; a rather



dark one gives the most pleasing results. Have it sufficiently long so that it can be placed under the dish and then curved upward to form the background. The lighting should be as uniform as possible, as deep shadows, unless one has experience in this work, are sure to cause trouble. The colour contrasts will give sufficient brilliance to the finished slide. We have not mentioned that each sheet or 8 by 10 film cuts into nine pieces—approximately 3 3-16 by 2 3-8. Therefore, when composing the view it is best to use a mask not larger than 2¾ by 2. Just outside the actual picture space place a sheet of white paper, as this is essential for future reference. Focus sharply through the red filter, which is visually the brightest, and stop down till all is needle sharp.

The factors for Cramer filters with Cramer Spectrum Plates are fairly constant, only the red changing. The red is usually eight times normal, the green sixteen, and the blue four times. The use of an exposure meter (such as the Wynne, Watkins or Imperial), which actually tests the light, is urged. Having

decided the normal exposure, expose the plates each under its proper filter and mark the holders so that they can easily be identified. As these plates are extremely sensitive to red, only a green safelight can be used, and this cautiously.

The following developer gives especially good results on the above-mentioned plates:—

Water	8 ozs.
Kodelon	15 grs.
Sodium sulphite	60 grs.
Potassium carbonate...	70 grs.
Potassium bromide, 10 per cent. solution, (only if necessary).	5 drops

With a soft pencil, mark the edge of the plate exposed under the red filter with one line on the emulsion, that through the green with two lines or a corner may be marked with (R, G, or B) the letter designating the filter used. This will positively identify the plates if no mistake has been made in removing them from the holders. Place all three plates in one tray and pour on the developer, being sure to cover them quickly, as this developer is very rapid. At 65 deg. F. develop for exactly two and one-half minutes and transfer without washing to an acid fixing bath. When the plates are fixed, examine the images of the white paper, which should be the same density on all three plates. If this is not the case, make another set of negatives, but alter the filter factors. Once these are established they are correct for all plates of one emulsion number. A very slight difference in density will not noticeably affect the final result; in fact, the image of the red filter plate is often slightly less dense than that of the green. The appearance of these negatives will probably be disappointing, for they will be very thin, but that is the condition required. Also the exposure is better if over than under, as there must be no clear glass in any shadows.

We will now suppose that the fruit group mentioned is the object photographed. The first to be examined is the image of the white paper. Under a good light place a magazine page, holding the negatives about four inches above the page, the printing should just be visible through the portions of the white paper forming the highest light; a white paper in a shadow will, of course, be less dense. Now take up the red filter negative. The banana (if ripe) will be about the same or a trifle less dense than the white; the orange slightly less dense than the banana; the red apple (if very dark red) will be thinner than the orange; the green apple will be very thin. The green filter plate will show the banana about the same as the red filter plate; the orange will be much thinner; the red apple almost clear glass, and the green apple nearly as dense as the white. The yellow filter plate will show the banana, orange, and green apple very thin, and the red apple slightly denser. This appearance of the plates is only approximately correct, as the actual tint of the fruit varies, and the densities above given, while correct for the three plates we have before us, would in all probability vary with another group.

Sensitising the film for printing is the next step. As we do not depend on the silver in the emulsion we can open the film in any light. Do not expose it unnecessarily long to daylight, as it will, of course, darken, and this would affect the contrast of our print. Cut one sheet into three equal pieces. Immerse one of these in the following sensitiser, being careful to remove all air bubbles:—

Water	... 35 ozs.	1,000 c.c.s.
Potassium bichromate	... 315 grs.	20 gms.

When dissolved, add ammonia water till the colour changes from orange to lemon yellow. The solution should be stirred while the ammonia is being added. The sensitiser will slightly retain the smell of ammonia when the proper quantity has been added. The film should be bathed for five minutes at 60 deg. F. After required bathing, drain, and with a wad of cotton carefully wipe the back or celluloid side. This is very important, as any drops that may form on the back will affect the finished result. All these operations can be performed by gas or other artificial light, as the film is only sensitive when dry or nearly dry. Only sensitise as much film as is actually needed, as it will only keep for about three days, but for the first print it may be as well to sensitise more, for until you are acquainted with the printing and developing some is sure to be spoiled.

Carefully clean the back of the negatives. Make a Solio (P.O.P.) print from the red filter negative. When the highest light shows the slightest tint it is finished. Keep accurate printing time, as this is the test for printing the film. It is to be preferred that the print be made in the shade. If all the negatives are practically the same density only one test need be made. Now carefully clean with a soft cloth the celluloid surface of the film; any dirt or lint left on thia surface will show, as the print is made through the celluloid. Now cut the strip into three and place one of these pieces celluloid surface in contact with the gelatine surface of the negative and print for exactly the same time that you printed the Solio proof. Make prints in the same way from each of the negatives and place them in a box. As it is impossible to tell from the appearance of the film before dyeing, one from the other, it is necessary to mark them. When the print from the red filter negative is removed from the frame, cut a small piece from one corner: that from the green filter negative should have two corners cut. It is advisable to use as small a printing frame as possible. Around the edge of the frame build up to a height of about 6 in. a wall of black card or paper. This will prevent all but the direct light from acting on the print and will tend to give slightly sharper images.

The developing of these prints is done in hot water. It is of some importance that the temperature should be between 100 deg. and 112 deg. F. Heat the water to 112 deg. F., remove one film from the box, and clip in the centre of one end with a spring clip. Hang this on the edge of the vessel so that the film is entirely below the surface of the water. In about a minute the upper surface of the gelatine will be softened and begin to peel off, and by moving it gently about in the water all the gelatine not hardened by the action of the light will be removed, and the white image will gradually assume the proper contrasts. When the highest light is practically clear the development is finished, and should be checked by holding the film under a gentle stream of cold water. Now transfer the print to a dry clip and hang on a line to dry, being sure to remove all drops of water from the back of the print. Proceed with the others in the same way. If the films have been properly exposed they will develop only so much and then stop. This can be ascertained by holding the film above the water and watching the water that drops from a corner. This should show only the slightest traces of the gelatine emulsion. If under-exposed there will be large patches of clear celluloid showing where the lightest and middle tints should have been. If over-exposed the whites will not clear unless the temperature of the water is raised. Do not raise the water above 120 deg. F., as it is almost certain to crinkle the celluloid and render it useless. Under no condition should the gelatine surface be touched, as it is so soft that the slightest contact will mar the surface.

When the films are dry they are ready for fixing and staining. The fixing may be done in any convenient fixing bath that may be handy, but a weak solution of plain hypo with a small crystal of red prussiate of potash dissolved in it is to be preferred.

The dye baths are made as follows:—

Blue Dye Bath.		
Water	... 1,000 c.c.s.	35 ozs.
Methylene blue ...	... 2 gms.	3 grs.
Sodium carbonate ...	... 1 gm.	15 grs.
Red Dye Bath.		
Water	... 1,000 c.c.s.	35 ozs.
Basic fuchsine	... 2 gms.	3 grs.
Sodium carbonate ...	... 1 gm.	15 grs.
Yellow Dye Bath.		
Water	... 1,000 c.c.s.	35 ozs.
Tartrazine	... 3 gms.	4 grs.
Glacial acetic acid ...	... 10 c.c.s.	3 drms.

The dyes should be carefully dissolved in about 3 ozs. of warm

water and filtered into the larger quantity of water. After the films are fixed and washed they should be suspended in their proper dye baths. Be sure to move the film gently in the dye so that it will stain evenly. The film printed under the red filter negative (one corner cut) is to be stained blue, that under the green filter negative (two corners cut) is to be stained red, and the remaining film yellow. The staining requires some little time. If the dye baths are too strong the prints lack gradation, the lighter tints being heavy. If the dyes are too dilute the required depth of tint cannot be obtained, except by prolonged soaking. The blue positive is unlikely to give trouble. When stained to what seems to be the desired tint, dip a few times in clear water to remove surplus dye. If the whites are slightly tinted, bathe in water until they are clear and hang up to dry.

The red positive usually appears rather flat and heavy unless the dye bath is so dilute that the time of staining is unduly long. If it is too flat, bathe in clear water until the proper contrast and clearness of the whites is obtained; a little borax in the water will hasten this.

The treatment of the yellow film differs slightly from the others. The dye is very easily washed out; care should be taken that too much is not removed. When it appears correct, place in a solution of acetic acid, No. 28, 1 oz. to 10 ozs. of water. This serves to set the dye.

When the films are dry, place the yellow on the blue and carefully match the outlines. Hold with two clips and then register the red on the new green image. If all the steps have been carefully followed out, the transparency will show with startling accuracy the colours of the subject. If the tints are not correct it is usually an easy matter to pick out the trouble. If the entire transparency is of the correct or desired density, but shows a decided reddish or bluish cast, reduce them by washing. It is practically impossible to give instructions for corrections, but a little practice will enable one to pick out the faults and correct them. When familiar with all the details of the process it is very seldom that trouble will be experienced in adjusting the colours, as you will be familiar with the appearance of the different tints required to make any desired shade.

The mounting is done in the following manner: Dissolve some scrap celluloid in acetone or amyl acetate until the resultant solution is about the consistency of syrup. Cut from the black paper in which the film is packed a mask with the proper-sized opening. Carefully clean one side of a cover glass and fasten the mask to the glass by applying a small amount of the above cement to each corner. Adjust the blue print, gelatine side down, on the mask, and fasten in position temporarily with two clips; when in desired position cement the corners to the mask. After the cement has dried, carefully clean the celluloid surface of the blue print and superimpose on it the yellow print. It is best to use a magnifying glass to be sure that the two images exactly coincide. Cement this yellow print to the blue, and in the same manner adjust the red print, then bind up in the usual manner.

There appear in different publications the opinions of various writers as to the value of intensifying or reducing sets of tri-colour negatives. The various theories against the process do not seem to hold good. A negative that is too thin may give a slide that will be good in its values but still lacks the vigour and depth of colour desired; the obvious thing to do is to intensify. The tendency will be to overdo it, and here let us caution you that a very slight intensification is all that is required.

The following has been found to give excellent results, and may be repeated if the first treatment does not give sufficient density:—

Water...	4 ozs.
Potassium bichromate	20 grs.
Hydrochloric acid	40 minims.

Bleach thoroughly in the above solution; then wash in clear water until all traces of yellow chromate stain are removed, and develop in any developer you may have on hand. If pyro is used, give it an extra dose of sulphite so that the plate will not be stained. A short washing completes the process. Excessive density is best reduced by bleaching and washing as above and then partially developing the image. When developed to what you think is the correct amount, fix as usual and then wash. All these operations may be carried out in strong artificial light or screened daylight.

If the reader does not wish to go to the expense of purchasing the Cramer filters, the gelatine filters of Wratten and Wainwright will answer temporarily. These filters and the Wratten and Wainwright Panchromatic plates can be purchased from nearly all Kodak agencies.

The filter factors for the A.B.C. filters are given on a card which will be found in each box of plates. These plates have rather high filter factors, causing unduly long exposures, and are backed. This backing may be of advantage, but it certainly is messy.

The developer and time of development given on the card will probably produce more contrasts and density than desired, but if you wish to use it, use only one-half the quantity of each of the three solutions or use twice as much water. There is no reason why these plates will not produce results, but we have always used and had good results with Cramer's, and saw no reason for making a change.

No doubt the reader will consider this too much trouble, judging entirely from the lengthy explanation, but we assure him that the process is not a difficult one. We have, perhaps, gone more thoroughly into details than the average articles on colour processes, but there is much more that could be added were it not for making this too lengthy.

Our advice to anyone is to try the process. Time spent in making a successful slide is well spent, and perhaps you will conclude, as we have, that black-and-white pictures are no longer worth while. If the reader has at his disposal an electric arc light he need not wait for, or depend on, daylight for any of the operations of this process; in fact, for making the plates any light will be found suitable with the exception of the mercury-vapour light, which contains no red rays. If one has electricity, a properly arranged battery of nitro-tungsten lamps will give a beautiful light for the purpose. Those with a clear or ground bulb are desired, as the newer blue-tinted bulb acts as a filter, cutting down the red rays. The mantle gas lamps will also be found satisfactory, but rather slow.

The filter factors for Cramer filters using the Northern Arc are: Red, 8 times; green, 7½ times; and blue, 8½ times. For printing, the arc will be found more satisfactory than daylight, for if the distance in printing from the carbons is kept constant, the printing time for a set of negatives, once established, will always be right.

C. K. Teamer.
E. E. Miller.

Autochrome Reproductions.—The March issue of the "National Geographic Magazine," which is almost exclusively devoted to an illustrated account of the Ross-Smith aerial voyage to Australia, contains a section of full-page reproductions in colour of Autochromes by Miss Helen Messinger Murdoch, whose magnificent work in the Autochrome process was a feature of R.P.S. exhibitions a few years ago. Miss Murdoch has travelled over a good part of the world, and her colour photographs made in Ceylon and India, which here lighten the monochrome pages, provide an illustration of her skill in landscape as well as in portraiture. The half-tone three-colour reproductions have been exceedingly well done, though necessarily are not comparable with the originals for brilliancy and fidelity of colour rendering. The magazine is published at Hubbard Memorial Hall, Washington, United States.

A NEW GREEN SENSITISER.

[In the following note, published in the current issue of "Photographische Rundschau," Dr. E. König gives the first particulars of a new colour-sensitising dye which has special and greater sensitising properties in the green part of the spectrum, and is found to confer an advantage in practice in the making of the colour-sensation negatives for processes of colour photography or colour cinematography.—Eds. "B.J."]

At the present time there is no lack of red sensitisers. The red-sensitiveness of plates sensitised with pinacyanol or similar dyes fulfils all the requirements of photographic practice. Our aim of late years has, therefore, been not as formerly the improvement of red-sensitive plates, but the discovery of a specific sensitiser for green. From both the scientific and practical standpoints this long-desired dye has now been obtained in a new colouring matter to which the name of pinaflavol has been given.

Pinaflavol belongs to an entirely new class of basic dyes, and was prepared in the photo-chemical laboratory of the Höchst dye works by Dr. Robert Schuloff. The dyes of this series are characterised by their yellow colour and by their specific sensitising properties for the green part of the spectrum. Their behaviour towards acids is similar to that of the pinacyanols; they are stable towards acetic acid, but are decolourised by mineral acids.

Dr. J. M. Eder writes of the new dye as follows:—"In Pinaflavol we have obtained the long required green sensitiser, having a maximum at about the line E (wave length 530 $\mu\mu$) falling sharply to D and extending without gaps to F. In comparison with the eosine dyes Pinaflavol does not exhibit the unfortunate minimum in the blue-green, but yields a strong, even spectral band over the whole of the green, blue and violet."

As regards the sensitising curve of Pinaflavol, the rapid fall of the sensitiveness at D (in the yellow) is of special interest. In practice this fact is shown that in making an exposure on a coloured chart with a medium yellow filter the yellow-green is obtained stronger than the yellow. In orthochromatic photography there is, of course, no advantage in this, since yellow is visually lighter than green. Thus, for the preparation of orthochromatic plates the older sensitisers, erythrosine, ethyl-red or Pinaverdol are to be preferred. But in processes of three-colour photography the advantage is proportionately greater. As is well known in making a set of three colour-sensation negatives the red printing plate exposed through the green filter requires the longest exposure. The isocyanine or erythrosine plates hitherto used all possess a considerable sensitiveness to yellow and even to orange. It is, therefore, necessary to damp down the yellow and orange by means of the green filter in order to obtain the better effect of the green. But a green filter, on account of the density of all green dyes, absorbs a good deal of light, and, therefore, considerably prolongs the time of exposure.

Owing to its favourable sensitising curve, Pinaflavol allows of the red printing negative being made with a yellow filter; the filter requires only to fulfil the purpose of cutting out violet and blue. Inasmuch as yellow filters are of a high degree of transparency, the time of exposure can be reduced to at least one-half. This shortening of the time of exposure is of considerable value, not only to makers of three-colour process blocks, but also to those practising photography in natural colours, and particularly in colour cinematography, where any reduction of the period of exposure is an important advantage. It will thus be seen that Pinaflavol is an important addition to the available colour sensitisers, and represents a notable piece of progress in colour photography.

Pinaflavol is used in the same manner as the cyanine and isocyanine sensitisers The sensitising bath is made as follows:—

Distilled water	100 c.c.s.
Pinaflavol, solution of 1 part in 1,000 parts of water	2 c.c.s.

Plates are bathed in this sensitising bath for about two minutes in the dark, or by red light, allowed to drain thoroughly and dried. The sensitising bath compounded with a mixture of alcohol and water, as is largely employed with the isocyanine dyes, may also be used, but yields plates of a lower degree of sensitiveness. Experiments made in the way of combining Pinaflavol with other sensitisers have so far failed to yield good results. Pinaflavol is also suitable for the sensitising of collodio-bromide emulsion, for which purpose about 20 c.c.s of a solution of 1 gm. Pinaflavol in 1,000 c.c.s. alcohol are added to 1 litre of emulsion.

DR. E. KÖNIG.

IVES'S MEDICO-CHROMOGRAMS.—Mr. F. E. Ives announces that he has introduced a sufficiently truthful, simple and inexpensive system of colour photography for making records in medical hospitals, comprising a special stereoscopic colour camera, a simple fixed-focus copying camera for making transposed-image colour transparencies, and the Verak Stereoscope for viewing them in natural relief.

Technically a "two-colour" process, it is in reality a two-colour-*plus* process, by virtue of Mr. Ives's invention of the dichroic red-to-yellow print from the green-blue negative colour record, and truthfully renders the colours found in the class of subjects for which it is recommended.

The stereoscopic feature is most important in this kind of work, and involves no complication in the operation of the process. The images as seen in the Verak stereoscope are convincing re-creations of the subjects photographed, without "structure," and in true relief and perspective.

Two identical panchromatic plates are exposed simultaneously and developed simultaneously, producing the stereoscopic negative colour record, and the colour positives are made from these negatives by Mr. Ives's original and most simple photographic mordant dye process, converting the silver image to a transparent variety of silver ferrocyanide, which in turn mordants the respective colours from basic dye baths. Any desired number of the stereoscopic colour prints can be made from the original negatives; also lantern slides and paper prints. Particulars and prices are obtainable from Mr. Ives, 1,327, Spruce Street, Philadelphia, U.S.

AUTOCHROME PORTRAITURE.—M. Hervé, one of the veterans of the French Photographic Society, recently delivered before the latter body a short talk on the attractiveness of Autochrome portraiture by natural light out of doors or in the studio. While admitting that exposures ranging from 10 to 40 seconds were necessary in his experience for successful work, he nevertheless found that there were numerous graceful poses in which sitters found no difficulty in remaining motionless for such times. He advised that colours in the costume should be neither too dark nor too pale; light blue and mauve are especially to be avoided, whilst Japanese blue, dark green and bright red yield excellent results and a bright note of colour if used with discretion. He advised that direct sunlight should be avoided. Whilst in an open courtyard or garden an exposure of 10 seconds may be considered a normal one, 4 or 5 seconds will suffice on a sea beach, but in woodland surroundings, where the reflected light is predominantly green, 25 to 30 seconds will be necessary. M. Hervé gave these data as purely arbitrary and not in accordance with the indications of an actinometer. Yet in his experience they had proved a useful guide for relative exposures under different conditions. When using a lens of aperture *f*/10 or *f*/12, he would consider 20 seconds as approximately the normal exposure, which naturally could be greatly reduced by the use of modern lenses of larger aperture. A great deal of his work had been done, however, with a Dallmeyer lens of about *f*/10 aperture. He found it of advantage to make a pretence of exposing a plate in order to put the sitter at his or her ease through a long exposure. He found that sitters experience no difficulty in remaining still for the necessary length of time after having once or twice realised how long it was.

COLOUR RENDERING IN THE SCREEN-PLATE PROCESSES.

The taking of photographs in natural colours has become a fairly simple matter, but if these photographs are to have any value from the commercial, scientific, or pictorial point of view, it is most important that the colour rendering should be a faithful one. Colour degradation is often very pronounced in colour transparencies, due not to inherent shortcomings of the screen-plate processes, but rather to the neglect of fundamental principles in the technique of this branch of colour photography, and it is thought that perhaps some notes upon the causes adversely affecting the purity of colour rendering, and some hints upon the prevention of colour degradation, may be of use to those who are not very far advanced in this branch of work.

The defect most frequently met with in screen-plate colour photographs is colour degradation, due to the effect of coloured light-rays emanating from near objects finding their way to the plate, where their action adds a local, or general, tint to the transparency, to the detriment of the colour rendering as a whole. This phenomenon must always be watched for by the colour photographer, yet many seem to be almost unaware of it, especially when the action of the coloured light has affected the whole of the transparency. Colour degradation is often regarded as inseparable from the screen-plate colour processes, and though this is to some extent correct, the defect can be prevented to a much greater extent than it is.

Some time ago I was photographing a flower study, as is my usual custom out of doors, using an Autochrome plate screened in the ordinary way. When the finished transparency was examined, I was surprised to find that over the lower half of the picture there was a decidedly blue tint. At first leakage of light round the filter cell, or some small pin-hole not previously noticed in the bellows of the camera was suspected, but subsequent examination showed that the transparency was not fogged, or locally over-donse, as would be the case in the affected portion if either of the possible causes mentioned was responsible. There was nothing in the composition of the picture itself that could have given the blue tint. I noticed that a pale-blue twill background that I sometimes use lay rolled up just under the base board of the camera, and it was afterwards found in such a position that when the Autochrome was exposed it reflected a shaft of coloured light across the lens of the camera, giving rise to the colour degradation referred to.

If the colour contrasts of the subject are inclined to be weak, or the colours are among those best described as indefinite, or are mixtures of the primary colours, there seems to be a tendency for the more difficultly-rendered colours to lose their purity; such as when photographing a sitter in a white or cream dress against a lawn or hedge of a pronounced green colour. More often than not, the flesh tones, or the colours of the dress, will assume a decided green tint, caused by the strong coloured light reflected upon these weaker colours, from adjacent surroundings that may, or may not, be included in the picture. At the same time, I must point out that unless very difficult subjects are being photographed, or those presenting great extremes of contrasts in colour, a full exposure will often prevent this possibility. The worst cases of degraded colours that I have seen were upon plates obviously grossly under-exposed, and I would further add that the possibility of colour degradation is far greater when brightly-coloured objects are close to the lens than when they are included in the composition itself.

The great secret of preventing degradation of colours through the cause mentioned lies in having the lens adequately hooded, to such an extent in fact, that all light-rays are cut off that are not actually needed to form the picture. Not only must the photographer be on the watch to prevent coloured reflected light from near objects from spoiling the purity of the colouring of his picture, but in these days of anastigmats made to cover larger plates mounted in shallow mounts and fitted upon modern cameras possessing only the minimum bellows construction, scattered light in the camera, reflected upon the plate, has a very bad effect upon the perfection and purity of the colour rendering. This possibility can be prevented by having the lens well hooded. Many colour photographers seemingly ignore this to their own disadvantage.

The lens itself is not often looked upon as having any real bearing upon faithful colour rendering, and any of the modern anastigmats by reputable makers may be regarded as beyond question in the matter of its colour corrections. The R.R. lens, particularly if an old instrument, may give rise to trouble, by reason of the fact that it will not be fully corrected. In colour photography, more than in any other branch of work, the lens should be so corrected that *all* light-rays are brought to the same focus. The old R.R. lens will probably be hardly corrected for red rays at all, but the more modern instrument of this type may be satisfactory enough. In illustration of the shortcomings of a very old, though otherwise satisfactory, R.R. lens, in the matter of colour correction, I may mention that I once possessed one of these instruments that gave curious purple tones in certain areas of a colour transparency, while in compositions

containing red, such as a landscape with a few flowers of this shade in the foreground, these were always out of focus in the picture.

Another cause of false, or poor, colours in screen-plate colour-transparencies may be traced to the use of an improper colour screen, or one perhaps that has altered in its tint, owing to too much exposure to bright sunlight. A few hours' exposure to bright sunlight upon the front lens of a camera is sufficient to alter the tint of the filter used for at least one well-known colour process, showing the advisability of using the filter upon the back half of the lens, where this possibility is avoided. While on the subject of filters, I may point out that a lens filter suitable in every way for ordinary subjects and conditions of lighting may under exceptional cases be quite inadequate in its compensating power, thus allowing an excess of violet or other rays to pass through. When dealing with subjects that contain an excess of one colour, it has been found a good plan to supplement the deficiencies of the filter by the addition of another. In the case of a snow scene, for instance, the ordinary Autochrome filter needs to be supplemented by another, such as a K.2, in order to prevent the excess of ultra-violet light reflected by the snow from degrading the latter. This is a case where the lens hood is essential in preventing colour falseness from the excess of light. When dealing with subjects that contain extremes of colour contrasts, it has been suggested, as a good plan for preventing colour degradations and excessive green tint, to insert a special filter, with a view to absorbing the excess of that particular colour, for a certain portion of the whole exposure. I cannot speak from experience of this method, but recently M. Schintz, at a meeting of the French Photographic Society, demonstrated the value of various filters that he had employed for the purpose of correcting any general blue-green tint ("B.J." Col. Supp., February 4, page 8). This idea seems to be well worth following out. The filters used for colour photography are certainly open to improvement, and the plan mentioned above seems to suggest a useful field for experiment.

There is still another often unsuspected cause of poor colours upon screen-plate colour transparencies. I refer to fogging of the plate by too much exposure to the dark-room lamp during loading or development. Most workers hold the plate far too near the lamp. I firmly believe that the light-rays from the lamp, shining through the colour screen upon which the Autochrome emulsion is coated while the plate is still highly colour-sensitive, is often responsible for the viridian tint that so many colour transparencies possess. Though an Autochrome plate has a decided dip in its spectrum curve in the region of blue-green, many photographers are far too prone to take liberties in this direction. In conversation with a colour photographer recently, he remarked that his transparencies always had a green tint and therefore were unfaithful in their rendering. He was in the habit of developing his plates in the dark room, by the Virida light, and I suggested that this was probably the cause of the trouble. He replied, No, because the plates were not fogged. Subsequent conversation and the examination of his results proved that it was over-exposure to the dark-room lamp, and nothing else, that was responsible for the defect. I would emphasise the fact that if an Autochrome plate is slightly fogged through holding its colour screen through too close or too long an examination against the light of the Virida lamp, the effect of this fog or veil will be a tint of the same colour. In other words, what would be a slight veil upon a panchromatic plate will upon an Autochrome be invisible in this character, but will appear after reversal as indicated. All colour plates should be kept at least 6 ft. away from the dark-room lamp, using only the *reflection* of the light upon the glass side of the plate in order to see which side is which when loading or commencing the development of plates. After development has well started it will be time enough to note its progress; when the plate will be no longer so highly sensitive though even then caution is necessary. I always advocate tank development of colour plates, when the exposures are known to be correct, using a reliable time and temperature system. The plates may then be loaded into slides or the developing tank in complete darkness; in this way the risk of gog is minimised.

ROBT. M. FANSTONE.

THE PRIZMA PROCESS OF COLOUR CINEMATOGRAPHY.

For the first time films in colour, prepared by a photographic process and ready to show in any cinematograph projector, have been exhibited. They are by the Prizma process, which has been in commercial operation in the United States for the past two years and was recently introduced to British exhibitors at a private view at the Alhambra Theatre, and, a week or two later, to members of the P.P.A. Congress.

It must be emphasised that the process is a triumph of cinematograph colour printing. That is its most distinguishing feature. At the Alhambra the colour films were continuously projected for two hours, and represented a very wide range of subjects, from Niagara Falls and the Kilauea Volcano of the Hawaiian Islands to the making of a fashionable gown. Yet we must confess that the very first film, one entitled "If," biassed us against the process. It represented studies of fruits and flowers alternately in monochrome and in the Prizma colours. We have rarely seen such bad monochrome films. With so much to its credit, it was a very great pity that the promoters of the process should have thought it necessary to better their case by disparaging the monochrome cinematograph version. In controversy it is sometimes advised that if you have a bad case—abuse the other side. The maxim is rarely a good one, and considering how much there is to the credit of the Prizma films, more was certainly lost than gained by adopting it.

The leading feature of the process is, as we have said, that the films may be hired ready for exhibition in the projector of any cinema theatre. They are shown like any black-and-white film without the use of rotating colour screens or other special appliances. Therefore, providing that the process is capable of recording the picture plays which form the staple of cinema exhibitions, it follows that we are on the threshold of a revolution in the making of the pictures which form the entertainment of thousands of people every night of the week, a change; in fact, from monochrome to colour. Unfortunately, the films which so far have been shown—or at any rate those that we have seen—do not supply proof that the process can be applied to the making of picture play films. On the contrary, it would seem that the process is not yet adequate for this purpose. In every picture play film there is rapid movement, if not of the figures as a whole, at any rate of arms and legs, in even the quietest of comedies or dramas. It is a common defect of cinematograph colour processes that rapid movements in parts of the subject are accompanied by a fringing of strong colours along the outlines of those moving parts, due to want of identity between images which should be identical. Hence we naturally looked for this phenomenon in the Prizma projections, and could not help being struck by the fact that where human figures formed part of the subject their movements were most deliberately slow; or,

alternatively, if they were ordinarily rapid, were accompanied by this distressing colour fringing. Thus it would seem that so far as the making of the negatives is concerned, the Prizma process is still susceptible of improvement as regards obtaining identity in the pairs of images which in the subsequent positive film require to be brought into perfect register.

But as regards the technique of printing the promoters are certainly to be most heartily congratulated on having proved the practicability of producing colour-printed films on the commercial scale. The process by which the result has been obtained is a most ingenious one, and is a variation of the additive screen-plate principle embodied in the Autochrome or Paget plate, but so contrived that in the course of printing the structure of the screen is eliminated. It is not possible to describe the process in a few words, and there is, in fact, no object in attempting to do so, since the particulars are given in the patent specification, No. 129,638, of Mr. W. van Dorn Kelley, published in this Supplement only so recently as December 3, 1920, p. 47. The process has evidently passed through several stages of development since the date of the original patent of Kelley and Raleigh (No. 22,921 of 1914. "B.J.," June 2, 1916, p. 319). We have from time to time noted its progress in these pages (e.g., "Colour Photography" Supplement, April 6, 1917, p. 14; February 1, 1918, p. 8; and May 2, 1919, p. 20). Since so much progress has been made, it seems reasonable to suppose that those responsible for the technical development of the process will be able to bring the negative making to the same pitch of commercial perfection to which they have undoubtedly brought the printing.

PRINCIPLES OF COLOUR PHOTOGRAPHY IN SIMPLE LANGUAGE.

In a recent issue of the "Kinematograph Weekly," among the technical notes contributed by Mr. Colin N. Bennett, appears the following article on the basis of the so-called additive and subtractive systems of colour photography. Mr. Bennett so lucidly describes what is a stumbling block to many in the apprehension of colour processes that we must not let pass the opportunity to find a place for his paper in our pages.

With the resuscitation of efforts to commercialise colour cinematography questions arise in our minds which normally would not trouble us. We hear talk of "three-colour," and may wonder why the number of colours is thus arbitrarily kept down to three. Occasionally an inventor will write of "four-colour," or of multi-colour cinematography, and we then feel tempted to surmise he has *ipso facto* gone one better than the mere "three-colour" man, and that he will in consequence be able to show on the projection screen many pretty intermediate tints, which the worker with three colours only must necessarily miss.

Anyway, we ask, what is three colour? And why *three*-colour, seeing that the colours of nature are infinite in their gradation of shade and tone? With "Kinemacolor" we even had a two-colour process which, while by no means true to nature, was "not so bad." Certainly it showed on the screen more colours than two. All this is rather puzzling even to the experienced black-and-white worker who has never had to tackle colour theory. It is made still more intricate by there being for each colour process, two-colour, three-colour, or multi-colour, two ways of building up the colour effects. One way is to use coloured lights, and this is called the Clerk-Maxwell or additive method. The other way is to use coloured dyes or pigments. That is the Du Hauron or subtractive method. Moreover, the projection or printing lights or colours used with each method are entirely different. The Clerk-Maxwell additive colours are spectrum primaries. The Du Hauron subtractive colours are "minus colours," or reciprocals of the primaries, inasmuch as they are the tints which remain on subtracting one or other of the single primaries from white light. Thus, the man who plunges into the middle of three-colour theory without preparing his mind by a little suitable working up to it need not be surprised if he feels like a student starting upon the sixth book of Euclid before studying the other five.

The key to the whole problem of three-colour is in the very beginnings of it, and those beginnings were never connected with colour photography at all. To understand three-colour and the allied colour processes one must approach the theory as it was originally approached, not as a problem of picture-making, but as the explanation of a function of the human eye. The three-colour theory was originated by Dr. Young, an English oculist, about the year 1820, and further elaborated by Von Helmholtz some six years later. There is no evidence that either one was a photographer, and it is even doubtful if either would dare claim to be the "inventor of cinematography."

The Young-Helmholtz three-colour theory, as it came to be called, laid down that though the colours of nature are many, perception of them in the human brain is brought about by colour-sensitive elements in the retina of the eye, which elements are primarily able to differentiate no more than three colour-sensations, namely, bright ruby red, green, and deep blue-violet. According to this theory, yellow exists in nature, and may be isolated in the spectroscope as a pure colour, but for the human eye to transmit the sensation of yellow to the brain it has to adopt the device of equally energising the red sensitive and green sensitive retinal elements. In the same way, a blue-green would be communicated to the brain as a combined energising of the blue and the green-sensitive retinal elements. Dim colours such as "sad" green and bronze, are communicated to the brain by slight and simultaneous energising of all three colour-sensitive retinal elements in different proportionate amounts, according to the colour of the object.

So now we begin to see where "three-colour" gets its name. It is an acknowledgment of the Young-Helmholtz hypothesis that, whatever the original colour may be we see it is as a ringing of the changes on the proportionate energising of no more than three colour-sensitive components of the eye, and that these nerves are sensitive respectively to red, to green, and to blue-violet.

Not until 1861 did Clerk-Maxwell come on the scene and give the theory its photographic turn. Then he propounded that, acting on the Young-Helmholtz theory, if you could make a negative photographic record by red light, another by green light, a third by blue-violet light, and if you could project positives from the three records, so made one over the other on a projection screen, using lights of the same colour as those by which they were taken, you ought to be able to get what *to the eye* would appear to be a complete reproduction of the colours of nature. Clerk-Maxwell worked out the three slices into which the spectrum should for preference be cut. He made up appropriate colour filters (or screens of coloured gelatine which, on passing light through them, would filter out the colours not wanted), and he actually succeeded in demonstrating that his idea was intrinsically workable in practice.

Du Hauron, coming some fifteen years later, was more lucky, for he lived and worked in the time of the early beginnings of orthochromatism, or colour-sensitive emulsion making. The Du Hauron principles are at the bottom of all those present-day methods of three-colour where the image is built up not by mingling of coloured lights, but by the super-imposition of coloured pigments or dye images. His way was to work down from white to black instead of up from black (darkness) to white. So, instead of using simple primaries, he took from white light one or other of the primary colours, and worked with the colour which remained as the result of withdrawing that primary. If you take from white light its red component you are left with blue-green. If you take from white the blue component you are left with yellow, and if you take from it its green component you are left with pink. And so in ordinary three-colour book illustration, or when building up a "subtractive" film picture having the actual colours visible upon it, instead of arranging that the red record image shall be projected by red *light*, and so on, you arrange that the red record negative shall have a print taken from it in minus-red, or blue-green colour, that the green record negative shall have a print taken from it in minus-green, or pink, and that the blue record negative shall have a print taken from it in minus-blue, or yellow. With the Clerk-Maxwell method we have explained that the three beams of primary coloured light are projected, so that the coloured light images come in super-imposition, but with the Du Hauron method the pink, the blue-green, and the yellow image are printed, or placed, in accurate register one on top of the other.

And here we may see why the Clerk-Maxwell method is called additive, while the Du Hauron method is called subtractive. For with the three-coloured lights, it is the addition of one light to the other which builds up intermediary tones, and finally it is the addition of all three light beams together in the requisite proportions which gives *optical* (or simulated) white light, whereas with the Du Hauron method things are just the other way about. The

light coming through the high-lights of the Du Hauron colour film is an actual unobstructed white, while its filtration through the colour images one after the other, layer on layer, successively subtracts from this white light primary colour after primary colour.

And about four-colour and multi-colour? If what has gone before is correct, more than three separate colour sensations should not be necessary to build up the optical effect of every colour in nature. Nor would they be if it were not for the fact that both the green sensitive and blue sensitive retinal element are slightly sensitive to other primaries than those which serve as their main excitants. Of these, the green primary colour sensation is by far the worst (or most mixed). In other words, the eye does not see even the purest green as a single colour sensation, but as a multiple, or white-diluted sensation. The equivalent to it in subtractive colour work is that greens on their reproduction are apt to be bronzed, or rendered with an overlying sheen of browny-red. Hence arise numerous efforts to get greater purity of colour reproduction by sub-dividing the spectrum into more than three parts. It is a departure from the Young-Helmholtz theory, and partial return to the Wollaston theory, in the interest of the technics of colour reproduction by photography. Similarly, the two-colour process of colour cinematography, commercially called "Kinemacolor," was an heroic and quite remarkably successful attempt to blend the separate green and blue colour sensations into one for the sake of photographic and mechanical simplicity. Except for the fact that in this way you had to say good-bye to pure yellow, to pure blue, and to any pretence of violet, it did pretty well.

In Du Hauron four-colour, as applied to book illustration, the fourth "colour" is usually not a colour at all, but a grey or "neutral" key impression, its function being to supply body and outline to the colour printings that blend with it.

COLIN N. BENNETT

MECHANISM OF COLOUR PROCESSES.

AT the Royal Photographic Society, on Tuesday evening last, Mr. H. S. Watkins, a member of the Richmond Camera Club, delivered a lecture in which coloured lantern-slide diagrams were used more profusely and effectively than has previously come under our observation for the explanation of colour phenomena and the rationale of processes of colour photography. Some years ago Mr. E. A. Salt published drawings which explained the mechanism of the Autochrome process in the most explicit manner. But Mr. Watkins has had the ingenuity and patience to prepare coloured perspective drawings, making clear the principle of subtractive colour printing, by no means the easiest thing to do. And in respect to the Autochrome and Paget screen-plate colour processes he showed a series of enlarged lantern-slides with the filter units appropriately coloured for the purpose of exhibiting the structure of these mosaic colour plates.

The latter part of a lecture, delivered at a high speed, dealt briefly with the practical working of the processes, and the subsequent discussion ranged round a number of points of manipulation.

Mr. J. C. Warburg described the method he preferred to adopt for developing Autochromes, viz., in a glass dish placed so as to allow of illumination from below momentarily by means of a pocket torch lamp fitted with a green filter. It was thus easy to follow the change of appearance from negative to positive as development proceeded, but a developer which partially desensitised the emulsion was necessary.

Mr. D. E. Benson, referring to the defect of most colour processes in records of green sensation, drew attention to the need of investigation of the degree of variation in the gamma of negatives with the wave-length of light.

Mr. Raymond Crowther spoke of the superior smoothness of small stereoscopic Paget transparencies as compared with Autochromes.

Mr. Luboshey said he always used the pyro-ammonia developer for Autochromes because he required to see what he was doing, and he believed the ammonia had the effect of desensitising the emulsion.

Mr. K. Hickman pointed out the extra blueness of screen-plate transparencies was due to some red transmission by the blue filter units. He recommended cementing the transparency and viewing screen in the Paget process with Canada balsam.

Mr. Colin N. Bennett mentioned that phenosafranine acted excellently as a desensitiser of Autochrome plates.

A remarkably fine series of Autochrome and Paget colour transparencies by Dr. Rodman, Mr. Nelson Clarke, and Mr. F. R. Newens was shown.

News and Notes.

TRIADOCHROME COLOUR PROCESS.—In the "Acton Express" of April 29 last we find a reference to a process of colour photography which has been invented by Mr. John Frederick Shepherd, of 10, Derwentwater Road, Acton, formerly official photographer with No. 8 Squadron in German East Africa, and afterwards sergeant-instructor at the Air Force School of Photography, Farnborough. Little technical information regarding the process is given, but it is to have the name "Triadochrome," a designation which perhaps may have something to do with the principle upon which it is based. It is stated that many fine examples of the process have been shown in the shape of prints, among them colour photographs of West-end shop windows and of fashion studies. It is further claimed that the process is of such simplicity that the ordinary photographer will be able to print coloured photographs straight from his own negatives.

AUTOCHROMES AT BOSTON, U.S.—Boston, U.S.A., was fortunate, indeed, when, on March 18, in Steinert Hall, Fred Payne Clatworthy, the well-known Autochrome specialist and landscape photographer, with a studio at Estes Park, Colorado, gave an illustrated lecture on Autochromes. Mr. Clatworthy has made, during the past eight years, a large number of notably beautiful Autochromes of scenery in the National Parks of California, Arizona, Colorado, and elsewhere, forming a collection of 5 x 7 Autochromes which he values at $10,000. On the occasion mentioned he projected, on a nine-foot sateen-screen, eighty 5 x 7 Autochromes selected from his large collection. They were principally of Southern California, the Desert, and the Grand Canyon of Arizona. These Autochromes were remarkable for accuracy of detail and colour, particularly the most delicate shades of purples, browns, blues and other predominant colours. The plates of the Grand Canyon were unusual on account of their delicate blue, obtained during the early morning and the late afternoon. Remarkable for extraordinary fidelity and beauty was a series of sunsets with the ruddy disc of the sun just about to disappear and, having gone, colouring in a fiery red the underside of a bank of clouds.

Mr. Clatworthy prefaced his exhibit by projecting the first successful portrait Autochrome made, in 1907, by the Lumières, of a prominent merchant of Lyons, France, which, on account of its remarkable accuracy of flesh-tints and the hair and beard of the model, evoked hearty applause. This valuable historical Autochrome was presented by Antoine Lumière, head of A. Lumière & Sons, to Wilfred A. French, Editor of "Photo-Era," on the occasion of the banquet given by the latter in honour of M. Lumière in Boston, November 1, 1907. Although the plate has been shown to friends many times, by Mr. French, its colours retain their original brilliancy, purity and fidelity. Then followed projections of 5 x 7 plates of flower-gardens, ocean-views, mountain-scenery, old Spanish missions, cacti and wood-interiors, in great variety and of surpassing beauty—each evoking hearty expressions of approval.

Mr. Clatworthy has been giving a series of illustrated lectures on Autochromes in the East—the Brooklyn Institute of Arts and Sciences; the Columbian University, in the Camp-Fire Club and other clubs, New York City; and the University and Museum of Fine Arts, Philadelphia. He considers the Autochrome plate as the ideal process of rendering simply and faithfully the colours of Nature, oil-paintings, water-colours and all objects in colours.—"Photo-Era."

REMARKS ON RAYDEX.

Many failures in working this process, now successfully overcome, have taught the writer the mistakes usually made by novices. Raydex demands far more scrupulous accuracy in working than any other photographic process, with which I am acquainted, but, worked properly, it is absolutely reliable.

These few notes are written to supplement the official instructions, issued by the Raydex Company, in the hope that those who, up to the present, have not been successful, may be induced to give it another trial. We will therefore presume that the worker is all ready to commence operations with his three bromide prints, fully developed, fixed and washed, each on a separate piece of glass, standing on the work table within easy reach. The first step is soaking the colour sheets, and these should remain in clean water for four minutes after they have uncurled. Insufficient soaking at this stage makes the hot-water development difficult later on. Care should be taken to brush away airbells in this and the subsequent sensitising bath, as they give rise to insoluble spots on the finished colour positive. In all operations care should be taken to give all the colour sheets identical treatment, and, if we work in the order blue, pink, yellow, this order should be adhered to till the end.

When the soaking is completed, each colour sheet is pinned up to drain while the sensitising solution is made up. Trouble must be taken to measure out the two solutions *exactly*, and remember that chemical action between them starts at once, and therefore they cannot be made up until the moment that they are required. The first colour sheet (blue) is immersed in the sensitising bath, and, when cleared of airbells, pink, and finally yellow, may be put in, rocking the dish and turning over the sheets for the required time of sensitising, *i.e.*, two minutes. The whole secret of Raydex lies in the correct application of the colour sheets to their bromides, and the correct method is as follows:—

Remove the colour sheet with the right hand, coated side down, thumb on top. In this way it can be held firmly, but take care not to squeeze it, or it will be marked. Drain it from one corner for a few seconds, and take the glass holding the corresponding bromide in the left hand, fingers underneath, thumb on top ready to hold the colour sheet in position, once it has been applied.

Have a good flat squeegee ready to hand, lying across one corner of a dish containing clean water. The bromide is immersed, and at the same instant the colour sheet is slid under water, gripped in position by the left hand thumb, and the whole removed as instantaneously as possible, draining the water into a sink or a big dish placed conveniently for the purpose. Squeegee the two together, commencing from halfway down the colour sheet. Beginners at this process seldom realise how important it is to keep the water clear from colour sheet drainings. The solutions act very quickly, and even in a dilute form will gnaw away the half-tones, though the action is not visible on the bromide print. A good deal of practice with two pieces of paper is recommended in order to obtain the requisite dexterity in manipulation.

When all three bromides have been treated they are removed from their glasses in the correct sequence and superfluous moisture removed with blotting paper or chamois leather. They are then hung up for about twenty minutes. At the expiration of this time, the first colour sheet is separated from its bromide, the latter being placed straight away into clean water. The colour sheet is also dipped into cold water, and, held by both hands in a loop, is lowered on to the celluloid support and squeegeed lightly with a flat squeegee. The celluloid should then be placed on a hard, flat support—glass is excellent for the purpose—and the back of the colour sheet is most thoroughly dried with a roller squeegee and blotting paper. As soon as this is done it goes into the hot water. By the time the next colour sheet is ready for development the paper backing may be stripped from the first. Yellow is best developed by itself, but blue and pink may be developed together. Development is carried out by holding up the celluloids occasionally and draining off the soluble gelatine. In this development there are two important "don'ts."

(1) Don't always drain off from the same corner. The soluble gelatine partly protects the image underneath, and if we always drain from one corner the image would be perceptibly weaker in the remote corner. For this reason development in a vertical tank is not recommended.

(2) Don't have a lamp under the developing dish. The image under the heated part would be much thinner than elsewhere. The temperature can be raised by adding hot water from a kettle.

Frilling in development is caused by not having a safe edge round the colour sheet or by insufficient drying of the back before development. The remaining operations of Raydex are amply described in the firm's booklet, and it only remains for me to emphasise the necessity for a thorough cleaning between each transfer. Three applications of petrol should be made to make the transfer safe. I most cordially recommend the double transfer process, and those who have tried it will not willingly return to single transfer. There is one small point about double transfer, and that is to remember that the gelatine coating on the temporary support is very soluble and may be melted by the heat of the hands. For

this reason, when registering the second and third transfer, always endeavour to keep the hands off the image; and if this is impracticable, it is advisable to place a piece of paper between the fingers and the support.

It is only fair to Mr. Manners, the originator of Raydex, to state that all the foregoing information is due to him, and I feel that I should like to make some acknowledgment of the invariable help and courtesy I have always received at his hands. I am sure that other workers will experience the same.

H. E. RENDALL.

LIGHTING AND EXPOSURE IN AUTOCHROME WORK.

THE beginner in colour photography by the Autochrome process will not work very long without finding out how very important it is to give the correct exposure for each plate. Autochrome plates of necessity have a very thin film and consequently very little latitude in exposure. Correctness in this respect is of far greater importance than in any other branch of photography, since a slight error of a degree that would make but very little difference in the production of a good monochrome negative may be sufficient to cause the loss of the transparency in Autochrome work.

An exposure meter should always be used, preferably one of the Watkins or Wynne pattern, with a special dial adjusted to suit the needs of Autochromes, and the photographer should aim at great exactitude both in testing the actinic value of the light and also in giving the exposure indicated One of the peculiarities of the Autochrome plate is that in sunlight it gives a better colour rendering of the subject with very slight under-exposure, which saves the "burnt-out" or weak colours that are often in evidence with Autochromes taken in brilliant sunshine. When the light is weak, however, slight over-exposure will be necessary to produce correct contrasts. The meter makes a proper guide in this direction, and its reading should always be adhered to.

Some photographers I have met were under the belief that it is only possible to make good Autochrome pictures when bright sunlight is falling upon the subject, but experience has taught me that this is far from being the case; in fact, some of the best plates that I have ever taken were exposed in dull light. Also, a dull lighting tends to remove troubles from over strong contrasts in the lighting of the subject, since a dull or diffused light will be found to illuminate more evenly both shadows and high-lights. It must be kept in mind, however, that a dull light tends to soften the colours of the composition; but though this may be the case, the general effect, the delicate nuances and aerial perspective will be far better in their rendering, and possibly a dull light is what the pictorial colour photographer will choose.

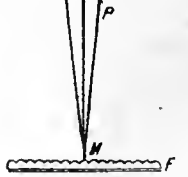
One fact must be kept in mind in connection with this. The Autochrome plate demands considerably more exposure between dull and bright light than is the case with ordinary plates, or, in other words, it is slower in dull light than under conditions of sunshine. This fact must be kept fully in mind when exposures are being made indoors; in fact, Messrs. Burroughs, Wellcome and Co., in their list of plate speeds issued for use with their "exposure calculator," give an indoor factor of 24, against an outdoor factor of 12 for Autochromes.

Under-exposure is fatal, since there is no cure for it; and this, in my experience, is the mistake usually made by beginners, and to which most of the failures in Autochrome work may be traced; and when the worker is in any doubt, more, rather than less, exposure should be given. An over-exposed plate will, of course, produce a thin transparency, weak in colours, though these may nearly always be restored by intensification. Some Autochrome workers always over-expose their plates, and rely upon intensification to bring the pictures up to the requisite quality. In my own experience, this is the only course when extremes of lighting compose the illumination of the subject.

Many workers using Autochrome plates are not perhaps aware that backing the plate with the white instead of the black side of the protecting card when in the dark slide reduces the exposure very slightly, an advantage when these slow plates are being exposed upon animals or objects liable to movement. I cannot say that I have tried this myself, so the exact extent that the exposure is decreased I cannot say from personal experience; and other workers with whom I have discussed the point seem more or less in doubt on the question. Dr. Lindsay Johnson, in his book "Photography in Colours," says the white card in contact with the film reduces the exposure to about three-fifths.

DYE-TONING IN COLOUR PRINTING.—A full patent specification, No. 160,137, by W. Van Dorn Kelley, inventor of the Prizma process of colour cinematography, has recently been made open to inspection before acceptance. It relates to the process of obtaining colour transparencies by bleaching the silver image and subsequently dyeing it. The silver image is bleached in a bath that will transform the silver into a compound which is not redevelopable by a reducing agent or developer, and then dyed in an acid or azo dye bath, which is mordanted only at the places *in situ* with the original silver. The silver image is first hardened by a formaline bath. The bleaching bath contains a copper or chromium salt or both. A bath instanced contains potassium bichromate, potassium bromide, copper sulphate, and hydrochloric or acetic acid. The image may then be treated in an acid fixing bath of hypo and sodium metabisulphite, or this may be done after dyeing. The dyes used are acid or azo dyes and ponceaus, fast reds, acid fuschine; and dyes such as used in wool dyeing, are instanced and give a choice of pure non-dichroic colours and a very transparent image. To brighten the colour a bath of ½ per cent. solution of sulphurous acid may be used. The process is used to obtain one or more of the component colour elements in a two- or three-colour photograph or cinematograph film. The components may be on separate films, or in separate coatings on one film, either on the same or on opposite sides.

A REFRACTING SCREEN-PLATE.—According to a recent patent, No. 158,511, open to inspection but not yet accepted, A. Keller-Dorian, Mulhouse, France, has claimed the following :—For colour photography there is interposed between the lens H and a plate F having a number of microscopic refracting elements M, a system of relatively inclined surfaces producing an interference spectrum. In the arrangement shown, a reflecting-prism P and optical flat L are used. Instead of being flat, the plate L may be slightly convex and touch the prism at the centre. Alternatively a set of thin reflecting-plates may be used, such as are obtained by the Lippman process.



TONING WITH METAL SALTS, PLUS DYES, IN COLOUR PROCESSES.

A REMARKABLE pink-toning process for the preparation of the red or pink component in a two-colour or three-colour assemblage method is described in a recent patent specification (No. 160,540) of W. Friese-Greene, J. N. Thomson, and Colour Photography, Ltd. The process is for use in colour-toning of one element of a resulting coloured photograph.

The term "foundation" as employed is used to denote any opaque or transparent negative or positive representation of the original object; and the purpose of the invention is to colour appropriately such a positive or negative foundation which has been obtained as the result of originally exposing a sensitive surface to the influence of light of one colour or one group of colours, and which is to be used as one coloured element in a two- or multiple-colour photographic process.

According to the invention, a toning solution comprises in admixture ferricyanide of potassium, nitrate of uranium, rose bengal, naphthol yellow, acetic acid and water together with iodine, and, in addition to or in place of the iodine, an isocyanine dye such as pinacyanol or Sensitol Red.

The invention further includes toning solutions in which the ingredients are in admixture in certain specific proportions.

It will be seen from the following description that some of the ingredients employed are dyes, whereas others are such as to have a chemical action by which the foundation is coloured in the required manner.

Two particular embodiments of the invention for the colour treatment of a foundation which it is desired to colour, broadly speaking, over a range of colours extending from yellows to deep reds are as follows:—

Ferricyanide of potassium	½ oz.
Nitrate of uranium	½ oz.
Rose bengal	¼ gr.
Naphthol yellow	¼ gr.
Iodine	¼ gr.
Glacial acetic acid	½ oz.
Water	40 ozs.

The rose bengal and iodine are together dissolved in 1 oz. of pure alcohol. The naphthol yellow is dissolved in 1 oz. water distilled, and these two solutions are then added to a solution obtained by dissolving the other ingredients in the 40 ozs. of distilled water.

In the second example the ingredients are present in the following proportions:—

Pinacyanol or Sensitol Red	¼ gr
Ferricyanide of potassium	½ oz.
Nitrate of uranium	½ oz.
Rose bengal	¼ gr.
Naphthol yellow	¼ gr.
Iodine	¼ gr.
Glacial acetic acid	½ oz.
Water	40 ozs.

It is not essential to the present invention that iodine be present, as it may be omitted entirely from the solution, but if it is present the above quantity is preferred.

It is preferred that the pinacyanol or Sensitol Red, rose bengal, with or without iodine, are together dissolved in 1 oz. of pure alcohol. The naphthol yellow is dissolved in 1 oz. distilled water and these two solutions are then added to a solution obtained by dissolving the other ingredients in the 40 ozs. of distilled water. For each ounce of solution used, add 10 drops of glacial acetic acid.

It is found that the solution described in the second example results in an improvement in the red colour tone obtained.

In either event, after the foundation has been toned with one or other of the above solutions according to the nature of the foundation, it will then be fixed by treatment in the following solution:—

Hyposulphite of soda	½ oz.
Metabisulphite of potassium	60 grs.
Water	20 ozs.

The above toning or colouring solutions are given as examples for the treatment of a foundation obtained as the result of originally exposing a sensitive surface which has been rendered specially or mainly susceptible to red light-rays; that is to say, the negative (or the positive) produced under these conditions will be acted upon mainly by those portions of the object, or by those objects, constituting the subject of the picture from which red colours, or the warmer-toned colours, emanate. Moreover, the solution is particularly applicable in those cases where a normal exposure under good light conditions has been made. The relative proportions of the ingredients in the solution will, however, be varied to suit the varying conditions under which the original exposure may have been made.

The resulting colour of a foundation treated with the solution above described will be generally, in normal cases, in the region of a rose-pink colour and can be used in a two-colour process in conjunction with companion foundation, to be superimposed in register upon it and coloured generally a blue or bluish-green.

It can also be used in a multi-colour process with other appropriately-coloured and superimposed foundations.

COLOUR PRINTS BY COPPER-MORDANT DYE-TONING PROCESS.

THE specification of a patent, No. 147,005, recently granted to Dr. Arthur Traube, relates to the process of dye-toning by means of a copper-mordant for the production of colour prints and transparencies. The original application, in Germany, under the International Convention, was made early in 1916, since which time working details of closely similar processes have been published by Mr. F. E Ives. Dr. Traube, it will be remembered, was the originator of the "Diachrome" dye-toning process, in which the mordanting substance was silver iodide. Apart from his present claim, his specification is of interest for its references to earlier work in the same field.

There is a known process for converting silver pictures into coloured pictures by application of organic dyes. Silver iodide is the best silver compound for the purpose; after the picture has been dyed with basic dyes it is fixed by an operation which removes the silver iodide and leaves a picture in dye only.

This separation of the silver iodide and the fixing of the dye in the form of a lake impairs the definition of the picture. By this invention it is possible to make a coloured picture from the silver picture, which, besides being highly transparent, has an undiminished definition.

It has been proposed (Patent No. 3,666, of 1915, "B.J.," Feb. 18, 1916, p. 103) to tone silver pictures with vanadium chloride and to colour with a basic red dye the yellow picture obtained. This process is only described for obtaining a complementary colour to bluish-green, but not for other colours, the latter being produced by inorganic toning without using organic dyes, the use of which would be in fact impossible. The present process allows the use of all basic dyes of every tint. It has also been proposed (Patent No. 10,893, of 1904, "B.J.," March 31, 1905, p. 254) to tone silver pictures with manganese salts and colour the obtained picture with aniline hydrochloride. The latter is not a dye, but an uncoloured chemical compound, the colour is produced by a chemical conversion of the aniline by the action of a manganic salt.

In the present process a similar chemical process cannot exist. Even if other manganese salts be used (Patent No. 21,584, of 1906, "B.J.," April 12, 1907, p. 275) the colours are produced by chemical interaction. The pictures with manganese compounds are only suitable for paper pictures, not for transparent three-colour pictures.

It is found that pictures made by toning the silver picture with copper consisting of already coloured silver double salts with copper, may be dyed with organic, basic dyes, the original colour tints being changed in any desired direction.

In particular, copper-toned pictures, which contain copper ferrocyanide as colouring matter, may be dyed strongly in this manner with organic dyes, the peculiar red-brown colour of the copper toning being suppressed by the majority of the applicable dyes, the colour of the latter prevailing exclusively in the picture. In consequence of this abnormal capacity of copper ferrocyanide for being dyed, the silver picture must be kept quite thin and soft if it is to be sufficiently transparent for projection purposes. The dyeing may be complete in about five minutes in dyes solutions of 1 : 1,000. The copper picture necessary for obtaining a powerfully coloured dye picture is so thin that separation of the copper compound is superfluous. At the same time, the definition of the original silver picture remains undiminished, and this basic picture which is dyed by the dye may remain in the finished picture.

The transparency of the coloured copper picture is very high. It may be still increased if the silver ferrocyanide, simultaneously produced in the action of known solutions, is dissolved by means of a weak soda fixing solution; the coloured copper picture is in no way affected thereby. When the silver salt is not separated, pictures of highest transparency and purity of colour may be made by coating the layer with a varnish, for example, a solution of dammar in benzene.

By way of example: After the silver picture has been converted into a copper-toned picture, it is dyed in a solution of methylene blue (1:1,000), advantageously containing some acetic acid, until the back of the plate shows that the picture is dyed through.

For projection pictures this happens on the average in five minutes. For thicker pictures some minutes longer are required. A short washing of the picture follows, to separate the excess of dye stuff from the gelatine layer.

It may be remarked that the process is very suitable for making pictures in natural colours by the three-colour principle; they are remarkable for their brightness, high definition and transparency.

In a later patent, No. 147,103, of Dr. Traube's, the use of the following classes of dyes is claimed in conjunction with the copper-mordant process. Thiobenzenyl, thiazines, pyronines, safranines, oxazines, and acridines.

INVENTORS' REWARDS IN COLOUR PHOTOGRAPHY.

A CERTAIN strain of thought which runs through the following appreciation of the French inventor, Ducos du Hauron, by Dr. D'Arcy Power in his magazine, "Camera Craft," is worth emphasising for the benefit of those attracted by the possibilities of invention of colour processes. Dr. Power stresses the slight rewards which pioneers in photography have obtained. It is a common fate, not in photography only, and particularly in colour photography. It arises not only from the conditions of our civilisation, but from the failure on the part of most experimenters to recognise the gulf which separates first an idea from its successful experimental accomplishment, and then, again, this latter from commercial success. In colour photography especially, this road from beginning to end bristles with obstacles, yet inventors as a rule ignore them, or see them through rose-coloured spectacles. Therefore, while it is far from our wish to discourage experiment, we are confident that we are giving good advice when we say: Count the cost; expect nothing; if anything comes to you, pocket your windfall and be thankful. But unless you have large backing, and can afford to be indifferent to money losses, forget your invention as a money-earning scheme. As an occupation for your leisure and surplus cash it will give you much happiness; as a financial speculation, the chances at Monte Carlo are to be recommended in preference. Within our own experience there have been many instances where this advice first has been ridiculed, and its value admitted after a few years.

The history of inventions is usually a tangled skein of ideas and experiments leading over devious ways to the final results, and when we state that this man invented the steam engine, this man the telephone, and that man the aeroplane, we usually are referring only to the final perfection.

In the history of photography something of the same sort is manifest, and yet more than in other cases it is possible to put our finger on certain names, and say without much contradiction, these are they who have made possible what we now possess. If we go back nearly a hundred years, we may point to Nicephore Niepce, and say, "Here is the man who first made a photographic image and laid the basis of photo-engraving as we practise it to-day"; to Daguerre, and say, "Here is the man who gave us photographic portraiture"; and when we speak of Louis Ducos du Hauron, even more emphatically may we state that to him almost alone we are indebted for the whole development of colour as a part of photographic processes.

It is an interesting fact that, whatever may be the doubt in regard to the history of discovery, that of discoverers is in no such obscurity, and one of the most notable things is that very few of them have personally benefited by their work. These thoughts arise on reading of the death of Ducos du Hauron, who died recently in great poverty in France. When we think of the enormous capital and profits realised from photo-engraving, and learn that Niepce's son was only too glad to receive from the French Government a miserable pension of three hundred dollars a year for his rights; that Daguerre was content with very little more; and that Ducos du Hauron, with a contribution to practical science and wealth production that is covered by the whole field of three-colour printing, Lumière plates, Paget plates and all the modifications of these that are yet to come, was given the starvation sum of two hundred and forty dollars a year, we have ground for believing that public appreciation and justice, in so far as inventors are concerned, is rather diminishing than otherwise.

What was it that Ducos du Hauron did? As a young man of twenty-five, back in the early sixties, he perceived that the only way in which the problem of photography in natural colours could be solved was to analyse the luminous image, register the different coloured rays, and, by their re-combination again, form a replica of a natural object. Whether this were to be by mixing the rays themselves, as we see in the Ives chromoscope, or by superimposing three colour images, as is done in three-colour half-tones, or by superimposition of coloured films, as in the Sanger-Shepherd transparency, or by the many modifications of these fundamental methods, or lastly, by the entirely successful intermingling of colour elements, as seen in the Lumière Autochrome, the Dioptochrome and the Paget colour plate, the ground principle is the same, and Ducos du Hauron not only laid this down as a basic theory, but foresaw the various way in which it was to be ultimately applied to give us the practical methods of to-day. Every inventor from that day to this has worked on his basis, and yet he himself was hardly known, even to the average photographer, and his reward was neglect and poverty. We have shown what the Government did for him—the manufacturers who realised their great profits did, it is true, throw him a pittance from time to time; but the fact remains that he died a poor, almost hungry, old man. If it be asked how such a condition was possible, we have to reply, for two reasons: his thought preceded the conditions that could make it practicable, for, while he demanded colour-sensitive emulsions, there were none available at that time; secondly, he had no commercial ability, nor the persuasiveness to induce those who had the capital to use it in the development of his ideas, nor had he protected them from those who ultimately exploited them. In this he but repeats the story of inventors in many other fields. If there be one thing which is demanded in justice to the men who think out the future, and to the benefit of society at large, it is that the present system of patenting, or the present patent laws, be revised, and that the State be obligated to help those who are developing useful ideas, and to reward those who can demonstrate their claim to prior invention, whether the commercial application has been brought about by themselves or others. Lastly, we have to thank Ducos du Hauron for laying down the principles of the motion picture, whose final perfection in colour is again a product of his prevision.

The details of his life are unimportant to us, but its results are a stimulus to every serious worker in photography, for the problems of the present and the possibilities of the future are no less alluring than the successes of the past.

CLOUDS IN AUTOCHROMES.—It is generally known that one of the weak points of the Autochrome process lies in its rendering of cloud effects, and very few indeed are the transparencies seen with really good sky renderings. Of course, this is largely caused by the smaller margin of latitude in exposure allowed by the Autochrome plate. Cloud formations, when very distinct, may sometimes be retained if a very exact exposure is given, and if care is taken not to develop the plate too far in the first bath, the requisite density and brilliancy of colour in the transparency being obtained by intensification. This plan, however, is more or less risky. A good way of preserving cloud forms is to paint over the sky portions of the plate with 10 per cent. potass bromide solution, using a sable brush very lightly charged with the solution. This should be done before the time of development as a whole is half complete. This is not an easy matter in the dim Virida light, though it should be remembered that by the time development has reached the stage mentioned the plate has lost much of its sensitiveness, and no harm will result if quite a bright light is used, provided the plate is not held too near. This method applies only in part to sunset sky effects, when, as a rule, the exposure is made with a view to including the clouds only, the landscape as part of the subject being of little importance, its effect being for the most part suggestive, as a silhouette foreground. Yet this must not be overdone, or an untruthful effect will be produced. Unless the landscape foreground is a very open, distant one, no details of it should be hoped for, since the quality of the sky effect would of necessity be sacrificed. In sunset sky effects, compromise with regard to exposure could be productive of successful truthful, or even convincing, results, and the usual exposure rule should be reversed to suit the case, viz., "Expose for the high lights, and let the landscape take care of itself."—R. M. F.

COLOUR CINEMATOGRAPHY BY ADDITIVE PROJECTION.

[A recent patent specification, No. 156,980, of Mr. E. C. S. Parker describes the details of an instrument serving for both the taking and projecting of two-colour or three-colour cinematograph film-pictures. The two- and three-negatives (impressions from which are afterwards united) are taken simultaneously.—Eds., "Colour Photography Supplement."]

The cinematograph film—hereinafter for convenience called the "film"—is commonly made of some standard width. The width of the picture is somewhat less than the width of the film itself. The height of the picture, measured in the line of travel of the film, is equal to the extent of forward movement of the film at each projection exposure. Projecting machines are commonly built to operate a film of standard width over a certain distance at exposure. To illustrate, at the present time films are usually made 35 millimetres, and the pictures thereon 25 millimetres in width. The height of the picture is 19 millimetres, and the extent of movement of the film at each projection exposure is the same.

It will be apparent that given unit film area and projecting machines built in accordance therewith, changes either in the width of the film or in its extent of movement at each exposure will require changes in the projecting machines, which for economic reasons it is desirable to avoid.

The first condition of the problem is that the film width and its extent of movement—or, in brief, the unit film area—must be kept unchanged.

The second condition is that there must be produced on the film the largest possible picture—or, in other words, the whole unit film area must be utilised.

The third condition is that the final picture projected on the screen shall result from a recomposition of several pictures of the same object simultaneously, and not successively, projected.

The fourth condition is that the projected picture shall be in natural colours.

The fifth condition is that the apparatus, which used as a camera produces the picture on the film, may also be used as a machine for projecting the pictures.

The sixth condition is that the optical parts of the apparatus, namely, the lenses or prisms and the light-filters, shall be stationary.

The seventh condition is that the parts of the apparatus shall be few, simple, easily adjusted and inexpensive to manufacture.

All of these conditions (it is claimed) have been met by the invention which comprises first the simultaneous production of similarly deformed pictures of the object side by side upon each unit area of the film, and then the simultaneous projection of deformed pictures through a deformer to reconstruct the final projected pictures in normal proportions. By interposing light-filters of different colours in the path of the light-rays which produce the deformed pictures, and projecting the deformed pictures through similar light-filters, the projected pictures are also reconstructed in natural colours.

In carrying out the invention the deformed pictures show the object as of reduced width but relatively unchanged in height. They are disposed side by side transversely across

Fig. 1.

Fig. 2.

Fig. 8.

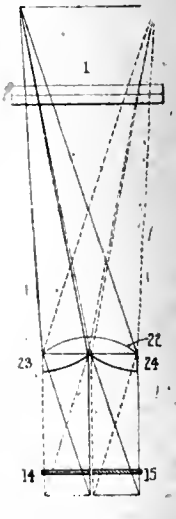

Fig 9.

the film and each picture is modified to transmit light rays of a different colour.

It has been proposed to reduce the size of pictures on cinematograph films, either in the transverse or longitudinal direction, to half the size of those at present in use, with the object of decreasing the cost of production of such pictures, and this has been effected by the introduction of cylindrical lenses or by one of several prisms into the optical system; each unit area of the film thus contains two different pictures, allowing two or more different subjects to be pre-

sented on a single film of normal dimensions, which partial images on each unit area of the film obviously could not be used for re-constituting a single projected picture in natural colours. In the present invention two or more deformed pictures of the same object are disposed side by side on the film and the two or more deformed images are simultaneously produced and simultaneously projected.

In the drawings—fig. 1 is an optical diagram, showing the apparatus arranged to produce two pictures simultaneously upon the film and to reproduce the pictures as a single picture in colours on the screen. Fig. 2 is a similar diagram of the apparatus arranged to produce three pictures, and to reproduce the same in like manner. Fig. 3 is a perspective view of lens 1. Fig. 4 is a perspective view of one of the lenses 2 or 3. Fig. 5 shows a portion of a film on which is a single picture of the object (here the letter X) photographed in the usual way, with relative dimensions unchanged. Fig. 6 is a portion of a film on which are two pictures of the object, of which pictures the height is unchanged but the width is reduced one-half. Fig. 7 shows three pictures, with their

Fig. 3.

Fig. 4.

height, as before, unchanged, but their widths reduced to one-third.

Fig. 8 is an optical diagram similar to fig. 1, showing a modified form of apparatus. Fig. 9 is an optical diagram, as before, showing another modification. Figs. 10 and 11 illustrate certain lenses of the apparatus of fig. 9. Fig. 12 is a modified arrangement of the dividing lenses of fig. 9 to produce three pictures, and fig. 13 shows a mode of producing the lenses of fig. 12. Fig. 14 illustrates a portion of a completed film as produced and projected.

Similar numbers of references indicate like parts. 1 is a

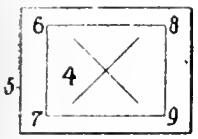

Fig. 5.

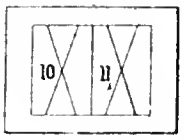

Fig. 6.

Fig. 7.

double convex cylindrical lens, 2 and 3 are similar lenses but of less width, placed parallel to one another and perpendicular to lens 1, as shown. In fig. 5 there is shown a single picture 4 produced on the film 5 in the usual way. The optical field is represented by the area 6, 7, 8, 9, which contains the object here represented by the large letter X.

The area 6, 7, 8, 9 is termed for brevity, the "unit film area." With the lenses disposed as stated, the light rays from the object will be divided into two pencils or groups, one of which will produce the picture 10 and the other the picture 11 on film 5, as shown in fig. 6. The height of the object in these pictures is the same as in the picture 4. The width of each object is reduced to one-half the width of the picture 4. The width of each object is reduced to one-half the width of the picture 4. Consequently the two pictures 10, 11 unitedly occupy exactly the same unit film area as does picture 4. The width of film 5, therefore, remains the same, the extent of movement thereof at each projection exposure remains the same, and the same projection machine will project the two pictures simultaneously upon a screen.

If three lenses 2, 3 and 12 are used, as shown in fig. 2, then three pictures 10, 13, 11, fig. 7, will be produced on the film in the same unit film area, but, of course, reduced in width to one-third of that of picture 4. And so, generally, we can add to the number of similar dividing lenses as we may desire, thus increasing the number of pictures in the same unit film area as that covered by picture 4.

All of these multiple pictures are deformed—here reduced in width—in the same way and to the same extent. All are produced simultaneously, and all are projected simultaneously. All—no matter how many their may be—occupy the same

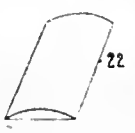

Fig. 10.

Fig. 11.

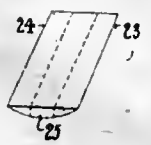

Fig. 13.

unit film area. The individual pictures of the group within the unit film area are motionless with respect to one another.

In order to project the pictures of a group occupying the unit film area, the projecting light-rays are first caused to traverse the pictures and then pass through the lenses, thus reversing the former direction of the rays from the object through the lenses to the film. The two deformed film pictures will thus be again deformed, and so caused to reconstitute the single picture of the object, as shown at 4, in normal relative proportions.

In order to cause this single picture to appear in natural colours, there is interposed in the paths of the rays light-filters 4, 15 of different colours. Thus filter 14 may be red glass and so cut off green rays, and filter 15 may be of green glass to cut off red rays. One of the pictures 10, 11 will, when traversed by the projecting light, stop out the red rays at certain parts, with the result that the final single picture on the screen will appear in natural colours as closely as can be approximated by the reproduction of the reds and greens in the object and their combinations. When the third lens 12 is added, a third light-filter 12* of some other colour—say blue—is supplied. The resulting screen picture will then reproduce these three colours of the object and their combinations. As each picture of reduced width, in the unit film area, gives the whole optical field of the object—more or less narrowed—it will be apparent that the greater the number of pictures produced in the unit film area, the greater the number of light-filters also used; so that the number of colours may be increased, and in this way the final single picture may be caused to reproduce with increasing accuracy the colours of the object.

As the pictures on the film will be negative, they should be changed to positive in the known way before projection.

The apparatus described may be modified in various ways to produce the same results. In the form shown in fig. 8, in addition to the double convex cylindrical lens 1, a single

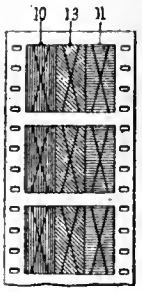

Fig. 14.

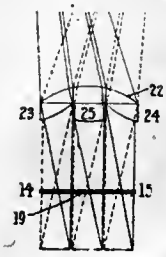

Fig. 12.

cylindrical lens 2 is used, in rear of which are two prisms 16, 17, with their corresponding edges opposed and separated by a gap 18. The rays passing through the portions of the lens overlapped by the prisms are deviated thereby, while the remaining rays pass directly through the gap 18 to the light-filter 19. In the paths of the two outer pencils,

there is disposed prisms 20, 21, which deviate the pencils and direct them respectively through the light-filters 14, 15. Here three narrowed pictures are produced on the film, which are projected as a single picture in natural colours upon the screen in the manner already described.

In the form shown in fig. 9 a plano-convex cylindrical lens 22, fig. 10, is employed to the plane side of which are cemented two lenses 23, 24. These lenses are alike and are produced by dividing a plano-cylindrical lens, as 22, into two longitudinal half sections on the dotted line as shown in fig. 11. The lenses are placed with their edges abutting as shown in fig. 9, each lens then covering one half of the plane surface of lens 22. The light from lens 1 traversing the lenses 22, 23, 24 will then become divided into two groups or pencils of rays, and hence, as before, will form two narrowed pictures on the screen. The light-filters 14, 15 are placed as before, and the operation of the apparatus is the same as already described.

In fig. 12 is shown a modification of the dividing lenses of fig. 9. To produce these, the lens 22 is divided longitudinally (fig. 13) into three sections 23, 24, 25, and the section 25 is placed, as shown, between the sections 23, 24. The rays are thus divided into three groups, and traverse three colour filters 14, 15, 19 to produce three narrowed pictures on the film.

Fig. 14 represents a portion of the completed film with three groups I., II., III. of three pictures. The film is fed through the projecting apparatus in the usual way—the group II. succeeding the group I., the group III. succeeding the group II. and so on. The colour rays which the differently light-filtered picture of each group will allow to pass when projected are indicated by vertical, diagonal and horizontal line. Thus the pictures 10 will allow only red rays to pass (vertical lines), the pictures 13 only green rays (diagonal lines), and the pictures 11 only blue rays (horizontal lines). Hence when the film is fed onward a red picture of one group is followed by a red picture of the next group, and so on for the other colours. It will, therefore, be evident that the colours on the screen are not produced by the superposing of different coloured pictures belonging to different groups and requiring a feeding movement of the film to effect this; but that, on the contrary, the pictures of each group are simultaneously projected to produce the final coloured picture.

The pictures of each group occupy the unit film area—the same as occupied by a single picture 4, fig. 5, produced in the ordinary way. No increase in the length of the film over that normally used for such single picture is, therefore, required. No change of any kind is made in a standard film adapted to receive single pictures, or in the mechanism in common use to project such a film. In event of breakage of the film, there is no more possibility of error in rejoining it than in any monochrome single picture film. The relative position of the several pictures 10, 13, 11 forming a group is invariable, so that there is no way of displacing one with reference to another and so throwing out the synchronisation, as inevitably takes place when breakage occurs in films where the constituent colour pictures are successively superposed upon the screen. Finally, but one shutter is required.

PICTORIAL PHOTOGRAPHY IN COLOURS.

Many workers regard colour photography only from the purely technical or scientific point of view, and few indeed are the transparencies or colour prints seen in the exhibitions that possess any great value as pictorial photographs, or indicate that their producer has endeavoured to infuse any artistic feeling into his productions. Certainly here and there we do find exceptions to this almost invariable rule, but the fact of the matter is that the practice of colour photographic processes may be traced almost entirely to an interest in the technical side, followed possibly by a fuller realisation of the value of good technical colour photography applied to some scientific branch of work very far removed from the artistic, which perhaps appeals only to the few. Another reason for this fact is that the photographer who works from purely æsthetic motives has not often the requisite technical knowledge or the inclination to acquire it, that is essential to successful colour photography. At the risk of entering upon a controversial topic it may be said that many embryo pictorialists seek to produce pictorial photographs before they have fully mastered the technique of their craft, and many of their results show technique so manifestly bad that the photographs produced actually give far less æsthetic pleasure to some than do the really beautiful technical photographs by a skilled commercial worker. This is a digression, but I think that such is necessary in order to point out that in attempting pictorial photography in colours successfully a sound knowledge of photographic technique in general is an absolute essential. The other aspect of the subject I propose to deal with very briefly in the following paragraph.

The photographer who has a grasp of pictorial precepts and has made some essays in the production of photographs that are distinctive in their conception and treatment will find upon attempting to express himself in colour, that he has different ground to cover, much to learn, as well as much to unlearn. As photographers we are so intent upon viewing our pictorial compositions through a mental vision that is devoid of colour considerations that the reverse order presents considerable difficulties in practice. Frequently we come across subjects, very attractive in themselves, that are quite impossible as monochrome simply because their appeal lies in the subtlety of their colouring. It might be thought that these are the ideal subject for representation by colour photography, but this is certainly not the case. Rare indeed are the occasions when a subject has been passed over as a monochrome composition, will it for the same reasons be ideal as a subject for a fine colour picture. Often it will be found that if a subject is attractive in monochrome it will also be of value for colour photography, always provided that it does not cover too large an area. The distant panoramic view is no more likely to be successful as a pictorial colour photograph than it would be as a monochrome subject; in fact, in this latter case the chances of success are all the greater, since hand work may be introduced, or combination printing may be adopted, with a view to putting in some foreground object that would "throw back." The distance of such does not conveniently come within the angle of the lens at the time of exposure.

The ideal subject for pictorial representation by colour photography must be discovered by every worker for himself, since only very general rules can be given. Care must also be taken in selecting the material for colour compositions, not to overlook the technical demands of the process, since the production of perfect work will depend to a very great degree upon the technical quality, no matter how attractive the subject itself, which may be beyond the capabilities of the process employed, for reasons too lengthy to be entered upon here. In regard to the pictorial aspect, one or two main points may be indicated as essential.

Both the subject itself and its composition should be simple, that is to say it is better to concentrate attention upon a single tree or bush of distinctive contrasting colours than to include in the composition a sketch of woodland of varied

hues. An area of a few yards will often furnish a more distinctive colour picture than some vista of beautiful colouring, no matter how satisfying to the eye this may be. Colour photography cannot express in a few square inches what in nature occupies perhaps several hundred thousand feet in extent: the reduction of each individual spot of contrasting colour is so great that unless very brilliant or distinctive the contrast cannot be as strongly emphasised as it is in the original. In cases like this the most satisfactory course will be for the photographic pictorialist to take some part of the composition, such as the effect of light, or colour contrast, upon a bough or group of flowers and foliage. If the worker will consider this carefully, he will, I am sure, see the force of this argument, also bearing in mind that old dictum pressed upon the beginner in pictorial photography, about the part being greater than the whole. Of all the failures in colour photographs, from the pictorial standpoint, most could be attributed to the photographer attempting what is obviously more than his medium is capable of producing satisfactorily, while of all the colour photographs produced and exhibited during the last few years those depicting quite simple subjects have been more consistently successful than those that attempted to portray large expanses of landscape, such as a painter would immortalise upon a large canvas. For this reason, a simple study of still life or a simple, though studied arrangement of flowers of contrasting colours, is often far more attractive as a colour-photograph than a landscape subject, and this class of work is ideal for pictorial photography in colours. I may mention that this branch of the subject was dealt with at some length in an article published in the "British Journal" "Colour Supplement," November 5, 1920.

The colour photographer seeking pictorial compositions will have another distinct point to keep before him. When producing monochrome photographs, only "form," and, to a lesser degree, tone, in rendering the contrasts and colours of the subject has to be considered, but in colour photography, from the pictorial point of view, there are also in addition to the lines forming the picture, the harmony, contrast, and balance of the colours composing the picture, which will have a very decided bearing upon the success of the work from the artistic point of view. Monotony in any form is to be avoided, such as would be produced by large expanses of the same colour, with no contrast or the relief afforded by other colours, or even by lighter or darker shades of the same. Many landscapes, for instance, are composed simply of tones of green. In Nature, of course, there is plenty of contrast in such expanses, but when reduced down to the modest dimensions of a colour plate, such pictures are apt to give an "all-over-one" colour effect, if the term may be coined. That is unpleasing and monotonous in the extreme. Only last summer I was seeking for colour subjects along the banks of a disused canal and several quite good compositions had to be passed over for this reason. I then came upon a group of weeds (the name of these I am not enough of a botanist to know) blossoming in spikes of reddish-pink, combined with yellow coltsfoot, and though these occupied quite a small area in the composition they were sufficient to produce the required colour contrast and relieve the monotonous effect. Figures also help a landscape, and, if introduced, care must be taken to see that on the one hand they assume sufficient prominence, while on the other the mistake must not be made of over-emphasising the presence of the figure. A touch of colour may often be supplied by the introduction of a figure, and for this reason all models should wear bright and distinctive coloured clothing, such as will photograph well.

The pictorial colour photographer will do well not to neglect a careful study of the masters of painting, both new and old. I mean, of course, those who paint with fidelity to nature; and though some geniuses may appeal to the imagination of some with lavender sunsets and effects never yet seen by the vision of normal man, these are useless for our purpose. The value of a careful study of the old masters is difficult to over-estimate, since it brings a good idea of form and composition, a sense of colour and decorative design, which cannot but assist the photographer to a very great extent in seeking beautiful subjects.

Enough has been said to show that though the production of pictorial photographs in colours is not an easy matter, and not to be approached without a very considerable self-culture and education in artistic principles, there is a real possibility that, given care in the selection and treatment of the right kind of subject, works of the highest quality and of great beauty may be produced. Few of the best known of our pictorialists have seemingly credited the colour-photographic processes as of much value as a means of expressing the beauties of nature, and, as before pointed out, there is certainly room for a decided improvement in the pictorial quality of much of the colour work shown. Perhaps some pictorialist of the artistic cult will exercise his skill and discrimination in the pictorial side of colour photography and let us see something really worth while.

ROBERT M. FANSTONE.

News and Notes.

IMPROVING AUTOCHROMES.—It may interest colour workers to know that Autochromes which are weak and lacking in brilliancy can often be greatly improved by binding them up with a second colour screen, instead of the usual piece of plain glass. These I have obtained from old and useless Autochrome plates by simply washing off the positive, or film, under the hot-water tap. The layer containing the starch granules does not run, and when dry it is bound up, film to film, with the Autochrome. The positive is thus sandwiched between two colour screens. The result is a more granular and denser rendering than the original, but the colours are more intense.—L. M. LEVENTON, L.R.C.P.S.I.

COLOUR CINEMATOGRAPHY.—The daily papers have been telling us of a new process to be worked by Mr. J. Stuart Blackton. The "Star" man tells us in his report that "It may not be generally known that every dress worn by film artists has to be designed for colour most carefully. The light pinks, blues, greens, mauves, etc., may all photograph alike; but if the colour scheme is wrong in the dress, the result on the screen would be blotchy. Unless one has actually seen these dresses in the studio, one can have no idea of their beauty. The colour schemes will no doubt have to be slightly altered, but that will be an easy matter. The producer to-day knows what effect he wants to gain, and he has to blend his colours accordingly, often using colours different altogether from these he has in his mind. In the new colour photography this arrangement will be unnecessary. To give an example. A butler, or waiter, will wear the regulation outfit in the new film. In the studio to-day he looks a weird individual. His shirt front is khaki, so is his collar; so are his cuffs; so is his serviette. Dead-white material sets up 'halation'—a glittering effect—yellow photographs white. Our natural colours are far richer than those in America, and better results should be obtained."

DIRECT COLOUR PHOTOGRAPHY IN MEDICINE.—The demonstration of coloured lantern-slides at the Section of Dermatology of the Royal Society of Medicine (says the "Lancet") showed the possibilities of this new method for purposes of illustration and teaching. Uvachrome diapositive lantern-slides are made from the original films employed in a new process of natural colour-photography in which no screen is employed; the minutest details can thus be projected upon the sheet without the loss in accuracy caused by disintegration of the colours. The dyes used in the preparation of the films reproduce the original colours with remarkable accuracy. The process does not lend itself to mass production, but it is found to be of the greatest value for scientific purposes. The slides are at present prepared by the Austrian State Institute of Photography, which keeps expert photographers at the disposal of the Viennese hospitals and clinics, so enabling accurate colour photographs to be made of cases of special interest. The negatives provide a record for the hospital archives, and furnish medical lecturers with the slides of individual subjects which they need. It is proposed to carry out the same work in England for the benefit of medical authorities in the hospitals and universities. If, as the makers claim, the films can be satisfactorily reproduced on paper, they should prove very valuable for use in text-books and in original articles on rare diseases.

DESENSITISING AUTOCHROMES BEFORE DEVELOPMENT.

In consequence of their great colour-sensitiveness Autochrome plates have hitherto required to be handled in a very weak dark-room light. Even when the Virida safelights, which we have regularly recommended, have been used, it has been necessary to take every precaution for avoiding fog by protecting the plate, as far as possible, from the dark-room illumination, and, in fact, exposing it to this latter for no longer than is necessary for noting the time at which the image begins to appear. Even this observation, which is necessary for ascertaining the correct time of development, is of some difficulty owing to the weakness of the light.

It is, therefore, evident that it is of considerable interest to employ a process by which the colour-sensitiveness may be destroyed immediately before development, without affecting the latent image, and so allow readily of noting the action of the developer in a relatively bright light.

As is well known, this desensitising has been rendered practicable by Lüppo-Cramer through the employment of phenosafranine. The remarkable action of this substance has led us to carry out a wide series of experiments on the chemical substances which exhibit this property ("B.J.," June 17 and 24, 1921). After having examined a number of dyes and other various mineral and organic substances, we failed to establish any definite relation between the chemical constitution and the desensitising property, but we discovered that certain other compounds possess the power of desensitising. Among these are aurantia (the ammonia salt) in 1 : 1,000 solution and picric acid in 1 : 100 solution. In the case of aurantia the desensitising effect is comparable with that of phenosafranine, but without certain drawbacks. The staining of the gelatine film with phenosafranine is more persistent than that with aurantia, which is very rapidly washed out. On the other hand, phenosafranine not only retards considerably the appearance of the image and of development, but this retardation is not constant for a given exposure. With aurantia, however, development takes place practically in a normal and uniform manner.

The desensitising action of picric acid is distinctly less than that of the preceding substances, particularly for red and green rays, but nevertheless it is sufficient for conditions of lighting indicated below.

Comparative experiments with these three desensitisers have been carried out as follows:—The method of development based on the time of appearance of the image, was employed in conjunction with metoquinone developer and with plates which had been exposed under identical conditions, except that the exposures varied from one to another according to the values, $\frac{1}{3}$, $\frac{1}{2}$, 1, 2, 4, 6, etc., the time of exposure required for a normal result being taken as 1.

Each plate thus exposed was cut into two. One-half was developed under the usual conditions and the other was immersed for 30 seconds in the desensitising bath. Development of the desensitised plates was continued so as to obtain a result as close as possible to that yielded by the normal treatment.

In ascertaining the time required for the appearance of the image a diluted developer was used; that is to say, 5 ccs. of the normal stock solution of metoquinone or chloranol were diluted with 80 ccs. of water.

The stock solution is:—

Metoquinone or chloranol	15 gms.
Soda sulphite, anhydrous	100 ,,
Potass bromide	6 ,,
Ammonia, 22 deg. B.	32 ccs.
Water	1,000 ,,

¼ ,, ...	36	4	30	40	4	30	48	5 —	60	6	40

In dealing with plates which had been treated with the desensitisers, the illumination employed was either that of a candle or Pigeon lamp at a distance of 20 in. from the dish, or obtained with a 16 c.p. bulb in a dark-room lamp fitted with six Virida yellow safelight sheets and placed 1 metre (40 in.) from the dish.

After having counted the number of seconds which elapsed after insertion of the plate in the developer for the appearance of the first outlines of the image, 15 ccs. of concentrated developer were added, and development continued, whilst also continuing counting, with the back of the plate turned towards the source of light, when it is not indispensable to observe the image in order to note the progress of development.

The times required for the production results as close in character to each other as possible are set out in the accompanying table. The figures shown for phenosafranine are averages, since the results with this desensitiser varied considerably from one plate to another, although the conditions of manipulation remained constant. The table thus emphasises the fact of the considerable advantage of aurantia for the desensitising of Autochrome plates over other desensitisers.

RELIEF PROCESSES FOR COLOUR WORK.

Little attention seems to have been paid to any other process for obtaining reliefs for colour transparencies and prints except that founded on the action of light on dichromated colloids, as in the carbon process. But there are three others which merit practical trial and with which excellent results are obtainable. The following notes have been compiled for another purpose, but it was thought that possibly there might be some who would be interested in the subject. The full references which have been given will enable anyone specially interested to go to the fountain sources in all cases.

The first process may be called the peroxide or etching process, as one uses hydrogen peroxide as the chief agent and the gelatine is etched away by the same. The first suggestion of such a method was made by R. E. Liesegang,[1] who found that a concentrated solution of ammonium persulphate so acted upon gelatine, in which finely divided silver was embedded, that it became soluble in warm water; but he also found that the action was a little unreliable. This action had been observed both with gelatine-chloride and bromide prints; bleaching took place, and on placing the treated prints in warm water and gently rubbing with the warm hand the gelatine was dissolved on the exposed parts and there was thus left a relief. Colonel Waterhouse informed Liesegang that he had made repeated trials,[2] and failed, and the latter also had the same experience. In the first instance he had used an old solution, and in his later trials a freshly made one. He found that a solution that had been freshly made was useless, and suggested that it was advisable to make a saturated solution and keep it for a fortnight in an uncorked bottle; if the solution was too old the whole film might dissolve. The negative to be used must not be intensified, and better results were obtainable with slightly under-exposed plates developed with a non-staining developer. The use of paper negatives was specially commended, and Liesegang said that the reliefs obtained could be stained up for making colour pictures.

M. Andresen[3] improved upon this method in that he abandoned the use of ammonium persulphate and used hydrogen peroxide. He also pointed out the shadow-reducing action of this liquid, obviously speaking of prints. He says "by the action of hydrogen peroxide on the silver image, produced in gelatine, the densest parts are first attacked, and in such a way that from the surface of the film there appears a gradual solution of the silver with the gelatine in which the silver particles are embedded. This processes can be utilised for the reduction of gelatino-bromide negatives that have been developed too hard. Of far greater importance, however, appears to be the fact that gelatine-silver images treated with hydrogen peroxide show when dry a marked relief, which can find application in the collotype process."

The solution recommended by Andresen was the commercial 3 per cent., to which was added 2 per cent. of pure hydrochloric acid. The negative should be immersed therein, and on rocking the dish there will begin, after about 5 or 10 minutes, a dissolution of the gelatine image, first in the densest parts, and the process will be complete in about 20 minutes. If there are somewhat large surfaces of density, then it is advisable to soak the negative in 5 per cent. alum solution first. The process is claimed for application to both negative and positive images.

I commenced to experiment with ammonium and potassium persulphate in 1910, and then tried out the peroxide and found that better results were obtainable by adding a very small quantity of bromide to the solution, and finally came to use cupric bromide. The work was dropped for a short time, and in the meanwhile a French patent[4] by E. Belin and C. Drouillard was published, which again roused my interest. These inventors cited the state of the prior art and the difficulties that had been met with, and pointed out that the action of the peroxide varied with the temperature of the solutions, and that the gelatine was dissolved the more quickly the higher the temperature. And, they stated, "one is induced to cause this rise in temperature in the molecule itself, and by the oxidation of the silver, which is embedded in the gelatine. It is evident that an oxidising agent or reagent creating a rise in temperature of the exothermic reaction would enable one to conduct the attack so that the points of the same opacity shall be dissolved before the regions less opaque are attacked. With this combination there will be obtained an etching of the phototype proportional to the opacities, and executed in a moderate time and under control, whilst the white parts are not attacked. At the same time it is possible to introduce into the action agents which shall swell and harden the gelatine in such a way that finally the cliché will be eminently suitable for galvanisation, which may be carried out in any well-known way. There will result then directly, without transfer, printing, retouching or other long and costly operation, a cliché immediately ready for printing. The solvent solution adopted at present as giving the best results is composed of hydrogen peroxide, nitric acid, potassium bromide and cupric sulphate in convenient propor-

Woch.," 1902, 386; "Jahrbuch," 1903, *16*, 386, accidentally discovered a process by which gelatino-bromide images could be converted into carbon images. A number of prints, which showed green fog, were placed in a solution of hydrogen peroxide diluted with three times its volume of water, and were left therein overnight. The next morning the images were seen to have completely disappeared, but on drying it was seen that the whites were covered with gelatine, whilst in the deep shadows there was no gelatine. The whole surface of the print was then painted with a brush charged with Chinese ink and dried. Then the paper was treated with warm water, on which the gelatine dissolved and carried the ink with it, whilst the shadows remained black, there was thus developed a correct carbon image. The process was found applicable to most papers.

tions. The nitric acid may be replaced by any other acid, such as sulphuric, acetic, etc. The following composition is particularly suitable for a regular etching:—

Hydrogen peroxide	12.5	c.c.s.
Cupric sulphate	50	gms.
Nitric acid	0.06	c.c.
Potassium bromide	0.02	gm.
Distilled water	1000	c.c.s.

Every developer can be used provided that the oxidation products do not tan the gelatine in the reduced parts. Ferrous oxalate mixed with one-third its volume of water is the best."

It was also suggested that if the iron developer were used the negative should be rapidly rinsed and the plate again immersed in the above solution, and the iron then retained in the depths of the film would be converted into ferric iron, which would harden the film. It was also proposed that a preliminary etching could be effected before development was complete, and then, after further etching, development proceeded with, and that this would enable deeper etching to be secured and that the gelatine would be at the same time so hardened that gentle friction with a swab of absorbent cotton could be resorted to without damage to the relief. The reliefs were applicable to photo-telegraphy and various other applications mostly of a photo-mechanical nature, and, amongst others, to tricolour typogravure. The claims of the patent are "A certain and rapid etching of photographic clichés (gelatino-bromide of silver) by the action of a bath of hydrogen peroxide, acidulated and mixed with a salt of copper and potassium bromide in convenient proportions. Application of the clichés thus produced and galvanised to all processes of reproduction."

H. Lüppo-Cramer[5] dealt with this subject, and called attention to the fact that the silver itself is not attacked when hydrogen peroxide alone was used, and that the addition of halogen ions showed a peculiar effect. The addition of bromides or iodides hastened the action considerably, and in such a way that by this addition a practical use of the reaction could be produced for the formation of reliefs. To elucidate this remarkable action he examined the reaction between silver and peroxide more closely, and found that the silver acted catalytically, in exactly the same way as iron or cupric chloride. According to Lüppo-Cramer's ideas there is formed, in the decomposition of the peroxide, oxygen in a highly dispersed form, and because of this and in consequence of the protective action of the extremely finely divided gelatine, the oxygen has an unusually strong oxidising action on the gelatine. The catalytic action of the silver is, however, adversely influenced if the silver at the limiting surfaces with the gelatines goes into solution, even if only in traces. This solution of the silver is prevented by the halogen ions, and these are thus indirectly the cause of assisting the velocity of the catalytic liquefaction of the gelatine.

Strips of glass plates were coated with colloidal silver gelatine and immersed in test tubes filled with the following solution: (*a*) 20 c.c.s. of 3 per cent. peroxide solution, plus 1 c.c. of 50 per cent. sulphuric acid; (*b*) the same solution mixed with a few drops of 10 per cent. solution of silver nitrate; (*c*) solution *a* mixed with a few drops of 10 per cent. solution of potassium bromide. Whilst the addition of the silver nitrate produced a strong acceleration of the dissolution of the silver and decolouration, in *c* the decolouration of the brown silver-gelatine did not take place at first, but there appeared in approximately five minutes a liquefaction of the gelatine, so that not only the plate alone but the whole solution in the tube became brown. Only after the whole film was dissolved did there appear a conversion of the yellow silver into white silver bromide. This experiment shows that the addition of bromide retards the solution of the silver but accelerates that of the gelatine.

The author's experiments with this process have shown that it is one well worth the attention of colour workers. It is, of course, obvious that, as with all other relief processes, great changes may be rung on the actual composition of the etching bath to suit individual requirements; but it must be recognised that Lüppo-Cramer's deductions hold good, and, therefore, the acceleration of the etching and its violence is easily under control. A moment's thought will at once show that this is an inverse process, that is to say, as it is the densely silver-covered parts that are etched, one must use a negative to obtain a positive relief image; and for this very reason the process seems to be more suitable for the amateur who desires to make either superimposed film pictures or imbibition prints.

The dense parts of the image being eaten away, there is left a relief in gelatine that corresponds to a positive, and, on dyeing up, the colour is absorbed in exact ratio to the quantity of gelatine present, and this dye-image can be used as a constituent of a superposed transparency or print or used for the imbibition process, that is, it may serve as a print-plate, and one does away with the tedious work of making both transparencies and print-plates, as in the Pinatype process, if one uses the original negative. It may be advanced, and rightly, that one destroys the original negative and that one cannot use the same for other printing; but as a matter of fact the dyed positive may be temporarily converted into a black or dark positive by the temporary use of a complementary coloured filter, and thus a duplicate negative can be easily made.

The gelatine being dissolved under the action of the bath where there is or was silver the final relief is never quite free from silver halide, and the plate or film should be fixed in a chrome alum fixing bath, then, after washing, treated with a 5 per cent. solution of formaline and superficially rinsed and dried. This treatment removes the last trace of silver salt and leaves a colourless relief, which would be quite invisible but for a slight turbidity of the gelatine; this treatment, especially with the formaline, is not absolutely essential, but I have found it to be advantageous, as the gelatine is rendered much harder, and in many cases the staining up appears to take place better, possibly due to some mordant action. With regard to the turbidity, this is the best term that one can use, and it is caused by the pitting of the gelatine; as each individual particle of the silver image is surrounded by gelatine there is left a pitted film, each little silver grain leaving a little crater or hollow, and these may be looked upon as acting like microscopic lenses, which cause different refractive effects, or possibly diffraction. This causes no trouble either when the results are superimposed as prints or as transparencies, and in the latter case there is no visibility on the screen, normal magnification being, of course, assumed. It may happen that a slight reticulation of the gelatine makes its appearance, but this is only occasionally noticeable, and usually disappears after the formaline bath. The main trouble, and this only appears when working with some plates, is the stripping of the film in the greatest densities, and this is obviously due to the silver deposit being so deep in the film that the etching action loosens the adherence of the gelatine to the glass, but this can be overcome by the use of the alum bath as suggested by Belin and Drouillard. In film work this is never met with. There is, as will have been gathered, no hot water treatment, and there is consequently with films much less chance of distortion and want of register through irregular expansion and contraction of the base.

Developed Relief Processes.

Probably the inception of the idea of obtaining relief images by development is contained in J. W. Swan's patent[6] for producing photo-relief plates, in which development with pyrogallol and ammonia is described, and the plate subsequently placed in warm water, when the parts unacted upon

5. "Phot. Korr.," 1911, *48*, 466; "Jahrbuch," 1912, *26*, 487; E. Constet, "Mon. Phot.," 1903, 251; "Phot. J. Amer.," 1916, *55*, 389, recommended developing with ferrous oxalate and immersion of the negative in ammonium or potassium persulphate till the image bleached, and then gentle friction with a brush to remove the gelatine, the immersion in an alum bath and drying, and subsequent staining up and the transfer of the dye to gelatinised paper

6. E.P. 2969, 1879.

by light and developer swelled up. But L. Warnerke[7] protected a process "for the production of negatives and transparencies where the parts unacted upon by light and development are dissolved away." For producing the film a colloid, such as gelatine or dextrin, should be supported on paper or other suitable material, and the sensitive salt might be produced by the emulsion or bath process, and exposures might be in the camera or otherwise. The developer recommended was a mixture of pyro, ammonium bromide, ammonia, citric acid and glycerol, alcohol and water. The image might be fixed or not, but in the whole treatment care must be taken that no substance, such as alum, is used that would produce general insolubility of the gelatine. When dry, the picture was placed in contact with glass and plunged into warm water. The picture adhered to the surface, and that part of the film that bore no image dissolved away. The image would be reversed, but that could be overcome by the use of transfer paper. Enlargements could be used and insoluble pigments might be added to the emulsion if desired. For relief elichés to be used in printing surfaces the sensitive film must be sufficiently thick, and a grain might be produced by adding an inert powder.

It will be noted that Warnerke used no sulphite. The reason for this was that he desired to obtain the full effect of the tanning by the oxidised pyrogallol, and this naturally leads to the conclusion that if the oxidation of the developing agent is more or less prevented, there will be control of the height of the relief. Silbermann[8] points this out, and says that it is well known that in the development of negatives there is produced a more or less marked relief, which, among other things, depends upon the developer. Pyrogallol, eikonogen, hydroquinone, and amidol give a strong relief; metol and di-amidophenol a low one, and glycin and rodinal practically none. There does not appear to be any connection between the constitution of the developer and this fact, but *p*-amidophenol is not suitable for relief formation. That the insolubility of the gelatine is dependent on an oxidation process is clear from the fact that the presence of sulphites is prejudicial to the formation of the relief. Although Silbermann does not quote any authorities, we must not overlook the fact that A. Haddon and F. Grundy[9] found that pyro solution had no tanning action on gelatine, but when the pyro was oxidised and became brown it exerted a strong tanning action and the gelatine became quite insoluble in hot water. After exposure to air, glycin and rodinal (*p*-amidophenol) did not affect the temperature at which gelatine dissolves in water; metol and amidophenol raise the temperature; hydroquinone, pyrogallol, eikonogen and amidol make the gelatine insoluble in boiling water. It was found that if glycin and rodinal were oxidised by bromine or similar agent the products tan the gelatine thoroughly, and the conclusion was that these two agents are not oxidised by air. When large proportions of sulphite are used in the developer the organic compound is very little oxidised, the gelatine is left soluble, and the relief of the image is very small. An image in high relief is formed under conditions which permit of the oxidation of the developer at the points at which it reduces the silver bromide, the gelatine at these parts being tanned by the oxidation products. This subject was also dealt with by A. and L. Lumière,[10] but it is not necessary to abstract their paper, which in the main confirms Haddon and Grundy's conclusions. The only point that is brought out is, that the oxidation product of *p*-amidophenol is insoluble in water and only slightly soluble in sulphite, therefore, the non-tanning action is explained.

News and Notes.

AIRCRAFT AND COLOUR.—Modern aircraft—aeroplanes, airships, and balloons—does not make pleasing screen-plate pictures, mainly because of lack of strong colours, and many colour workers no doubt read with great interest details of the vivid pink aeroplane which has been made for the Rajah of Morvi, and pictured in their minds colour-screen pictures of a blue sky filled with aircraft of various colours. The Rajah's aeroplane will no doubt be most effective when upon the ground, but, as a writer in the "Daily Chronicle" points out, at any altitude exceeding 2,000 ft.—which is quite low as aeroplanes fly nowadays—it is impossible to distinguish the colour of an object in the sky.

COPPER-MORDANT DYE-TONING. — Two patents of addition, Nos. 163,336/7, to patent No. 147,005 ("B.J." Colour Photography Supplement, June 3, 1921, p. 23) have been filed in London by Dr. Traube and are open to inspection before acceptance. According to No. 163,336, the pictures are treated, for the purpose of correcting and enfeebling the dyeing, with a dilute acid or for the purpose of intensifying the colour with a dyestuff solution. The reduction may be made before drying, but it is best to intensify only after drying. According to No. 163,337, the copper picture which is to be dyed is made by using a bath containing less than half the copper compound and potassium ferricyanide formerly usual. To further increase the transparency more potassium ferricyanide than the copper compound may be used. In the usual bath about equal quantities of copper sulphate and ferricyanide are used with about ten times the weight of either of potassium citrate.

CHRISTENSEN COLOUR SCREEN-PLATES.—According to patent specification, No. 163,311 (open to inspection but not yet accepted), of J. H. Christensen, the colour elements of a screen-plate are produced by comminuting (as by emulsifying) liquids containing a dye in such a form and under such conditions that mordanting does not take place before the elements have been applied to the under layer, the object being to avoid any decrease in brilliancy and clearness of the screen due to the complete or partial precipitation of the dyes. Also to make the screen water-repellent, the under layer on which the particles are coated is provided with a coating of a cellulose derivative with the addition of a basic substance, as, for instance, a soap, e.g., sodium oleate. For producing the screen elements, instead of aqueous solution of a basic dye mixed with tannic acid, the water solvent is partially substituted by methyl or ethyl alcohol, and in the case of a solution of tungstic acid, molybdic acid or phospho-tungstic acid mixed with a solution of basic dye, the liquids are rendered basic by the addition of ammonia which prevents precipitation. Where coloured basic particles of tungstic acid are used mordanting is effected by a subsequent treatment such as by an acid either in solution, or in the form of vapour. Inert substances such as gum arabic, dextrin, and albumen may be included.

THE PRIZMA PROCESS.—In writing of the trade demonstration of the Prizma process of colour cinematography in our issue of May 6 last, page 18, we referred to the apparent need, in the process, of a camera capable of producing identical images in the case of those negative records of the moving subject which require to be brought into registration when producing the colour film by an assemblage process. We further pointed out that the films themselves afforded evidence of the fact that rapid movement was deliberately eliminated from the subjects for the purpose of avoiding the colour-fringing effect which results from such absence of registration of images. We are therefore interested in hearing from the firm of J. Stuart Blacton Photo-Plays, Ltd., of Bush House, Melbourne Place, Strand, W.C.2, that a camera of this kind has been constructed by Mr. W. Van Dorn Kelley, the inventor of the Prizma process, and is being used at the present time for the production in colour of a drama film entitled "The Glorious Adventure." According to Mr. William T. Crespinel, who is in charge of making the negatives for this photo-play, the lens image is divided into three identical images in such a manner that the camera can be used with the same strength of artificial lighting as is employed for ordinary monochrome films. It is believed that the entire production of "The Glorious Adventure" will show that perfect colour registration has been obtained. If this turns out to be the case, it would seem that this film will be the first to have been produced under ordinary conditions of lighting and action for production in colour on the screen by photographic means.

NEGATIVES FOR THREE-COLOUR PRINTING FROM AUTOCHROMES.

In any descriptions of the Autochrome plate, which I have seen, it is assumed that the development of the film is confined to that part of it which lies immediately behind the starch grain which transmits the light. But considerable experience in making negatives for three-colour printing leads me to believe that this is not the case; but that grains adjoining those which transmit the light are also affected by it. And that this is the cause of certain difficulties I have found, which have not troubled me when working direct from nature.

The printing process I use is bichromated gelatine, and artist's colours in fine powder, spread with a brush on paper; printed, and washed off with warm water. But the difficulties would apply to any process. The trouble does not lie in the printing, but in making the negatives.

There are great advantages in using the Autochrome as the original colour record, instead of exposing three separate plates, especially when working from life or on landscape. But I have found that while I could always get a sky to print when working direct from nature I could never do so from the Autochrome until I adopted the device of backing the Autochrome with a very thin negative made by white light. This plan also gave a better separation of the colours in the case of flower subjects and such like. I was led to adopt it when trying to get negatives from a colour chart made by exposing an Autochrome plate to red, green and violet light in overlapping circles. It is a nice, bright chart with a white triangle in the centre, and blue, crimson and yellow outside that, and red, green and violet outside of them. Such a chart should in theory transmit an equal amount of red light through the whole of the red circle. It does not do so, but when examined through a red filter it is seen to pass more light through the crimson and yellow than through the red; and most of all through the white. And so with the other colours. And negatives made from it, even with filters of very short transmission, are more dense in the white than in the crimson and yellow, and least dense of all in the red.

Printing from such a negative—in blue, for instance—when the colour is all washed off the white, there is still some blue left on the red; and development has to be continued till that has been washed off. In the case of a landscape with white clouds and a red roof, if all the blue is washed off the roof too much is washed off the sky, where the development ought to have stopped when the clouds first became white. Working direct on such a subject no such difficulty occurs. In a flower subject you either get a bright red degraded by a little blue and yellow left on it, or, if you continue development until that is washed off, you lose the shadow detail in the white flowers.

By backing such a chart with a thin negative made by white light it is possible to get even density in the resulting negative over the whole of the red circle. But, of course, the backing negative has to be developed to exactly the right contrast to get that result, and therein lies the difficulty of using this device. There seems to be nothing for it but to make another if the first does not look quite right. I have met with some success in this way, but I do not pretend to be able to succeed at the first attempt every time. With practice I think one should do so. A negative much over-developed gives reversal, and can be recognised as likely to do so. But different Autochromes require negatives of different character. One that has had a short first development will want very little correction. But such an Autochrome is too dull to make a pleasing transparency or to be a good guide to the final appearance which your print should have. And, of course, one of the advantages of using the Autochrome as the original record is just that you have it to guide you in the final production of your print.

The explanation seems to be that if a plate is exposed to monochromatic light and developed and fixed, but not reversed, and then examined with a microscope, it will be seen that the starch grain is not entirely obscured with a continuous coating of black, but partially covered with very small black dots, and the adjoining grains, of different colours, also have a certain amount of dots over them; in some cases isolated, in others running in chains from the exposed grain. I do not know whether this is the case with other screen plates. But if it is caused by light reflected from the starch grains it might not occur in a screen of mosaic pattern.

Where there have been two exposures, as to violet and green light, the red grains are more heavily dotted where the two exposures cross, in the blue, than in either the violet or green, though they have had no exposure to red light.

The effect, where one exposure has been made, to one colour of light, is the same as if one grain had had a full exposure, and the other two a partial exposure. But in the case of compound colours, blue, crimson and yellow, two grains are exposed, and each gets a bit extra from the other. And in the case of white each grain gets what is equivalent to extra exposure, from invasion by the other two colours. The total result being the same as if the secondary colours had more exposure than the primaries, and the white most of all. It may be possible to produce a chart free from this defect. But for ordinary Autochrome work I have found my method

of correction a useful aid to getting good negatives. And I shall be glad if it is of use to anyone else.

It amounts to treating the Autochrome as being unevenly flooded with white light. Possibly the more correct method might be to back the Autochrome with negatives made by light complementary to that used in making the final negatives. But such trials as I have made of this plan seem to show that it is not worth the trouble of making three backing negatives, and the risk of one of them going wrong, in registration or otherwise.

As to the filters to be used in working from Autochromes I should be glad of any advice or assistance. I have used filters of short enough transmission to give no overlap. A very good and practical judge of colour printing tells me I should use longer transmissions. But I do not see why, nor have I found any advantage in filters of very short transmissions. After much experimenting with filter dyes I do not believe that a correct set of negatives could be made from colour charts such as mine, by any set of filters, without some such correction as I have used. But I shall be very pleased if anyone will show me a better way, or give any information on the making of three-colour negatives from Autochromes or any other screen plates.

E. A. Burchardt.

RELIEF PROCESSES FOR COLOUR WORK.

(*Concluded from page* 32.)

It is clear that in the use of sulphites we have a means of control of the height of the relief formed. From the author's experiments it seems immaterial whether ammonia or a fixed alkali be used, but for colour work the latter is much to be preferred on account of the more regular action. The actual composition of the developer is again of no particular moment, only such good results have never been obtained with any other reducing agent than pyrogallol. There are one or two points to which attention may profitably be directed. In the first place, the total omission of the sulphite gives a very high relief, which, as will be seen presently, is of no moment, but there is a tendency to the formation of a superficial skin of insolubilised gelatine that may later give a little trouble. The second and more important point is the absence of fog. As everyone knows, fog is metallic silver, and as the deposition of silver is accompanied by insolubilisation of the gelatine, it is obvious that a foggy result will not develop up into such a clear relief as plate that is free from the same; therefore, it is advisable to use a fair amount of bromide in the developer and to allow for this in the exposure, as it is well-known that bromide slows a plate, to use a current phrase.

In this process we have again the old carbon trouble of loss of half-tones, if one works in the ordinary way, that is to say, if one exposes from the front; and, therefore, exposure should be made from the back or through the support. And for this work films are decidedly to be preferred to plates, on account of their lesser thickness.

Stress has been laid, principally by F. E. Ives, on the importance of keeping the relief low, and if this is desirable then the sensitive film may be stained up with a yellow dye prior to exposure. For this purpose tartrazine, thiazol yellow or naphthol yellow can be used, or some other yellow colouring matter.

These three are particularly mentioned because they have been found efficient; the dye used must be of an acid nature, as the basic dyes have so little affinity for gelatine that it is almost impossible with many of them to say whether a film has been immersed therein or not. In the face of the most recent work on desensitising with dyes it is clear that not every one is suitable, but without examination of the question at all I think that most of the desensitising dyes are basic. The height of the relief is of not the slightest importance for superimposed films; when dry, the relief is so low that it is almost invisible, and I have never found any trouble when using such reliefs, even of the highest type obtainable on films in the imbibition process.

There is one point in connection with the use of dyed reliefs that seems to have been generally ignored, and that is the limiting absorption of the dye, and it is for this reason also that the deep reliefs are inocuous. To make this quite clear let us take the case of a filter dye, such as filter yellow K, and assume that we have eight gelatine sheets, all stained to the same depth. Then, placing one such film on a white support and superimposing a second, there will be noted a distinct colour change, and the same applies to the third, and possibly the fourth, this being entirely dependent on the dye density. But on superposing more films it will be seen that the colour change is very slight indeed; in fact, it is impossible to tell whether six or eight films are superposed. This state of things is met with in reliefs: the latter may be so great that the limiting absorption comes into play and the higher reliefs are visually obliterated. This can be best seen by the use of H. and D. strips; if, for instance, one has a strip showing clear densities in all nine sectors and a gamma of about 1.5, the positive here being in mind, when such is converted into a relief the nine steps can be seen, but when dyed up the number will be, perhaps, reduced to six. Practically the three densest reliefs are represented by the same colour visually, and no amount of soaking in the dye will alter this, although some slight variation may yet be detected in these three last dye densities by examination with a complementary coloured filter. This effect varies with the dyes, and it is impossible to state what dye will and will not give this result.

Reverting, however, to the question of the dye, it must also be taken into consideration that the easy removal of this pre-staining dye is advisable, but not essential; should any be left in the reliefs, it will merely make the reds a little more orange and the blues a little more greenish, which is quite immaterial in projection work, and it can be ignored in the imbibition, for if the dye will not wash out readily it certainly will not transfer easily. Another point that is of importance, although so much has been written on the particular dyes that are suitable for superposition and imbibition, that one may almost look upon this as supererogatory, yet it is as well to bear in mind in the temporary superposition of the stained films that examination should be made by the light that they are to be chiefly seen by; some pictures may look excellent by daylight and far too yellow by artificial light, and the difference is very marked sometimes.

Dichromated Relief Process.

This may seem an unhappy title, but I do not know what should be used, recognising that it may convey the impression of an ordinary carbon relief, and although dichromate is used light plays no part as the relief-forming agent.

Howard Farmer[11] proposed to treat developed silver images with dichromate, which he had discovered acted upon the gelatine *in situ* with the silver and hardened it just as though

11. E.P. 17773, 1889. It is quite possible that when using such concentrated solutions of dichromate some softening of the gelatine, not in contact with the silver, might take place, as strong solutions of the dichromates are good solvents for gelatine, and this property was utilised by J. Husnik in his "leimtype" process, see E.P. 73, 1887; 8,946, 1889; D.R.P., 40,766, 1887; 42,158, 1901; "Jahrbuch," 1888, **2**, 247; 1889, **3**, 75; "Handbuch," 1917, **4**, II., 215; "Silbermann's Reproduktionsverfahren," 1907, **2**, 185.

the light had reduced the dichromate; and later he ascribed this action to the catalytic action of the finely divided silver in the presence of the gelatine and dichromate [12]. The dichromate is reduced and the gelatine, by combination with the reduction product, is converted into the insoluble form. The silver itself undergoes no change. The simplest manner, he suggests, of observing this action is to immerse a plate or film with a silver image in a dichromate solution, when, if the strength be fairly concentrated about 20 per cent., the action is practically instantaneous. A more convenient means consists in preparing gelatino-bromide plates, in which the gelatine is retained in a soluble form, and developing the images with ferrous oxalate [13]. On placing the plates for a few seconds into a 20 per cent. solution of ammonium dichromate the gelatine, wherever it is in contact with the reduced silver, becomes insoluble, and the images, after washing, present the same relief as exposed carbon prints do when immersed in water. The chromated images also possess the same properties as dichromated images obtained by the action of light; thus the film, after drying and re-wetting, can be squeegeed to insoluble surfaces and developed with hot water, as is customary with carbon or Woodburytype reliefs, and the results have all the well-defined sharpness of the latter. Further, by heating the films, as in the collotype process, similarly reticulated surfaces are obtained on immersion in cold water. "These examples are sufficient to show that in the reaction I have described we are offered the means of obtaining for the chromium processes the high degree of sensitiveness hitherto only obtainable with the gelatino-bromide process."

Eder[14] considers the catalytic action as not quite satisfactory, as the metallic silver is changed for the most part, as chromic acid and dichromates convert it into chromate, the acid and salt being converted into chromium oxide, according to the following equation:—

$$6\ Ag + 5\ CrO_3 + 3\ H_2O = 3\ Ag_2CrO_4 + Cr_2(OH)_6.$$

This equation is only schematic, and in the presence of dichromate the reaction may be represented as follows:—

$$6\ Ag + 5\ K_2Cr_2O_7 + 3\ H_2O = 3\ Ag_2CrO_4 + Cr_2(OH)_6 + 5\ K_2CrO_4.$$

From numerous experiments I cannot accept Eder's last equation as correct, for although the matter was not especially examined there is no visible change on immersion of a silver image in dichromate solution. Namias[15] gives a much more feasible explanation; the best way of tanning the gelatine is to convert the chromic acid to a lower chromium oxide, and this can be and is done when the acid acts on metallic silver, and silver chromate and hydrogen are formed, according to the equation:—

$$6\ Ag + 3\ H_2CrO_4 = 3\ Ag_2CrO_4 + 6\ H.$$

The hydrogen reduces the excess of acid to chromium oxide, which, in the presence of the acid, becomes chromate of chromium, and it is this salt—

$$6\ H + 2\ H_2CrO_4 = Cr_2O_3 + 5\ H_2O.$$

that is the active agent in producing insolubilisation. The disadvantage of using chromic acid is that it not only suffers reduction locally, but generally also, so that the gelatine not in contact with the silver may be hardened, even if only to a small extent. Namias states positively, thus confirming my views, that the chromic acid in the dichromate cannot attack the silver[16]. It is rather beyond the scope of this note to enter more fully into Namias's paper, which deals with the reactions of the Ozobrome and allied processes, with which we are not directly concerned, though naturally the basis of the action is closely allied.

Namias comes to the conclusion that the best insolubiliser is a 0.5 per cent. solution of dichromate to which 2 per cent. of potassium bromide is added. If a solution of dichromate is acidulated with sulphuric acid, even if only faintly, the action is the same as if free chromic acid were used, and the silver image is rapidly bleached according to the equation:—

$$6\ Ag + 5\ H_2CrO_4 + 6\ KBr = 6\ AgBr + 3\ K_2CrO_4 + Cr_2O_3 + 5\ H_2O.$$

The gelatine *in situ* with the silver is then so hardened that the film may be placed in boiling water without any harm, and the image will stand a fair amount of friction. The effect with a sulphide-toned image should be greater still, because the sulphide must be first converted into sulphate and then into bromide, and there would be a greater quantity of chromium oxide set free, thus:—

$$3\ Ag_2S + 8\ H_2CrO_4 = 3\ Ag_2SO_4 + 4\ Cr_2O_3 + 8\ H_2O.$$

For years this valuable property of the dichromates appears to have lain dormant, and, so far as I am aware, no practical application of Farmer's own patent was made. W. Riebensahm and Posseldt,[17] after referring to Farmer's work, which, as they say, does not make use of a pigmented gelatine, propose to incorporate a pigment with the gelatino-bromide emulsion. The paper was to be exposed like bromide paper, developed in the usual way, and then, fixed or unfixed, immersed in dichromate and repeatedly washed and treated with ammonia to remove the last traces of chromate, and developed, etc., as an ordinary carbon print. The inventors state: "Das Verfahren ist auch verwendbar zur Herstellung von Bildern in natürlichen Farben, indem man nach dem Prinzip des Dreifarbendrucks Bilder in den drei Grundfarben herstellt und bei der zweiten Uebertragung aufeinanderklebt." Anglicised: The process is also applicable to the preparation of pictures in natural colours, as, according to the principle of three-colour printing, pictures in the three fundamental colours are prepared and superimposed in the second transfer.

J. Mézaros[18] patented a process for preparing pigments in monochrome, polychrome or natural colours and printing plates with a silver salt or an emulsion of the same, which was founded on Farmer's process. Ordinary bromide or chloride emulsion could be used and the positives made in the ordinary way, great stress being laid on thorough washing after fixing. The chromate necessary for the preparation of the pigment pictures was added afterwards to the gelatine and not used as a sensitiser. The silver image was immersed in a dichromate solution for three or five minutes and then the plate was immersed in a solution which would dissolve the image and at the same time fix the chromic acid in the film, and this would precipitate the metal in the form of chromate. For this purpose the film was immersed in a 2 to 3 per cent. solution of nitric acid, or the chromic and nitric baths could be mixed. The insoluble chromate precipitated in the image-bearing film in proportion to the shadows, combines with the gelatine, so that the image might be developed with hot water in the usual manner of carbon printing, and only the soluble parts are dissolved. A gelatine relief is thus produced which may be hardened in the usual way, and can be used for printing, or an electrotype can be made from it. The film of the image may be coloured with any convenient colouring matter to obtain a transparency, a negative for printing, or a positive on paper at will; or a precipitate may be produced in the gelatine of any desired colour, for example, sulphate of baryta, to make the image

12. "Phot J.," 1892, *32*, 30; "Brit. J. Phot.," 1894, *41*, 742; "Photography Annual," 1895, 221.

13. Ferrous oxalate was suggested because it was a non-tanning developer.

14. "Handbuch," 1917, *4*, II., 279.

15. "Jahrbuch," 1911, *25*, 140; 1912, *26*, 167; abst. "C.A.," 1913, *7*, 1681.

16. Abegg, "Jahrbuch," 1905, *19*, 108; Abegg and Cox, "Zeits. phys. Chem.," 1904, *48*, 725, state that potassium dichromate on solution in water undergoes dissociation into free chromic acid and monochromate. See also "Jahrbuch," 1912, *26*, 98.

17. E.P. 898, 1904, granted to Riebensahm and G. Koppmann; "Brit. J. Phot.," 1904, *51*; D.R.P. 153,439, 1902, to Riebensahm and Posseldt; "Jahrbuch," 1905, *19*, 456; "Silbermann, *1*, 241; "Phot. Chron.," 1904, 548; "Handbuch," 1917, *4*, II., 280; F.P. 338,170. The Neue Photographische Gesell. D.R.P. 196,962; "Handbuch," *loc. cit.*, 282, claim the addition of a hardening agent such as aluminium chloride to the dichromate bath. The addition of orthochromatic sensitisers is also claimed, E.P. 24,920, 1904; abst. "B.J.," 1905, *52*, 365, 873; D.R.P., 1904; Silbermann, *loc. cit.*, *1*, 280. Paul Pretsch, E.P. 2,373, 1854, used a silver salt in conjunction with dichromate for obtaining sunk or raised designs. Most readers will be familiar with the Carbograph paper which was on the market for a while some years ago.

18. F.P. 352,815, 1906; "B.J.," 1906, *53*, 434.

visible. When pigmentary or coloured images are required the necessary pigments should be added to the gelatine before the coating of the paper. It should be noted also that orthochromatic sensitisers may be added. With the new process it will be possible to obtain polychrome effects by super-imposing several films.

F. E. Ives[19] patented a process of producing multi-colour pictures by a process of "desolubilising" gelatine *in situ* with silver, utilising the action of chromic acid, and the superposition of the reliefs thus produced after staining up. He proposed to use a normal silver emulsion on a transparent support, such as glass or celluloid, and pre-dye it with a yellow dye such as tartrazine, to prevent the too-deep penetration of the printing light. The exposure was made through the back of the support, as would obviously be necessary, and a non-tanning developer was recommended. The hardening bath was:—

Ammonium dichromate	6.8 gms.
Potassium bromide	6.8 gms.
Sulphuric acid	6.5 c.c.s.
Water	1000 c.c.s.

The acid is said to be advantageous, as it enables the action to be washed as the image bleaches. The film was developed with hot water, and the silver salt dissolved out with hypo. The particular dyes recommended are Bayer's alizarine blue AS, equal parts of Bayer's rubinol R and rubinol 3G, and sulphon yellow R of the same make. To make a paper print, the blue constituent image was to be made on bromide paper and toned with cyanotype in the usual way, and this print was to be fixed in alkaline hypo, then rinsed and placed in a strong solution of oxalic acid. Presumably this was to convert some of the iron into hydroxide and dissolve out with the acid.

The author found that this particular bath gave rather strong contrasts, and that it had a tendency to eat out the finest details of the high lights. Namias's bath gave better results. There are, of course, all possible variations to be rung on this bath, and it will be found that slight variations of contrast are thus obtainable, and a few experiments will soon determine that which best suits the operator. It should, however, be noted that Ives's bath on standing, particularly in the light, develops free bromine, and that this may have a prejudicial effect, as it is well known that free bromine tans gelatine; obviously, any other halide may be used.

There remains but one point to deal with, and that is the printing; as this has to be done through the support, it is obvious that parallel light ought to be used, and for small work there is no trouble in rigging up a Mazda nitrogen lamp at the equivalent focus of a lens and getting over this difficulty; but, with films, if a lamp be placed at the bottom of a box about 4 feet deep, the inside being, of course, painted black, and a piece of opal glass be placed over the lamp, the results are so sharp as to bear considerable magnification, as the loss of definition is very little. For large sizes and glass plates one must use parallel light, but it would take up more space than is desirable, and I am afraid that even now this article has run rather beyond reasonable limits, or I would describe the elaborate but cheap apparatus that I have used. For similar reasons all instructions as to the particular dyes to be used has been omitted. Much has already appeared in the pages of the "B.J." on this subject, to which reference should be made.

E. G. Wall, F.R.P.S.

19. U.S.P. 1,186,000, 1916, Ducos du Hauron, Lumière, Sanger-Shepherd and Bartlett, and O. Pfenninger all disclose the use of non-actinic dyes in making carbon reliefs to prevent the too deep penetration of the light; but it may be contended that the two cases are not quite on all fours, as in Ives' patent we are dealing with a development process with a silver halide emulsion. Ives says: "I believe that I am the first to propose a photographic printing process comprising the incorporation with the sensitive silver in a suitable film of an actinic-light restrainer, whereby, upon exposure and development the silver image will be confined to one side of the film." But A. Hernandez-Mejia, U.S.P., 1,174,144, of March 7, 1916, date of application June 21, 1912, thus nearly three years before the date of Ives' application; which was March 13, 1915, says: "The gelatine or substratum, on that side is, if desired, dyed with a contributory colour (as yellow), one which when combined in projection with the red and green to make total opacity or black, a degree of colouring being employed which will not permit the actinic light, or will do so very sparingly, to pass through the film to the opposite side during the printing operation." This is a clear description of the restraining light action by a dye in connection with a silver emulsion.

TWO-COLOUR CINEMATOGRAPHY.

A process described in a patent specification (No. 165,826) of (the late) W. Friese-Greene and Colour Photography, Ltd., is of that type which consists in preparing pairs of negatives on a single light-sensitive surface, such as a cinematograph film, by exposing them in succession respectively to direct white light and through a coloured screen, preparing positives therefrom and thereafter colouring the positives so obtained (for projection) or projecting them through coloured screens.

According to the invention the exposure through the coloured screen is made through a screen coloured yellow, as for example through a screen coloured with flavazine.

For the purpose of projection in colour the entire positive surface obtained from the negative exposed directly to white light is preferably coloured approximately blue-green or is projected through an approximately blue-green screen, and the other positive surface is coloured, or is projected through a screen coloured approximately orange-pink or other colour of reddish-shade

In the preferred method of carrying the invention into effect, the cinematograph film is specially colour-sensitised as described in Patent No. 134,238 ("B.J.," December 12, 1919, p. 728). Alternatively, any other preferred form of panchromatic film may be employed.

The film is exposed in an ordinary cinematograph camera, fitted with a special shutter by means of which alternate exposures are made direct to white light and through a coloured screen or filter respectively. For this purpose either in front of or behind the usual shutter in the camera there is a disc of celluloid, which is stained over one-half with the required colour for the coloured filter. The other half is preferably opaque, and has in it a narrow slit. The disc is revolved with the shutter of the camera to expose successive portions of the film, alternately to white light and through a colour screen. The ratio of the width of the slit to that of the stained surface of the colour-screen is conveniently 1:5, so that the picture taken through the slit is very sharp, and that taken through the colour-screen is not quite so sharp. The result of this is that when the pictures are projected, the flickering usually experienced with motion pictures in colour is considerably reduced.

In the preferred form the colour screen is made of transparent celluloid coated with gelatine containing flavazine by the use of the following dye solution:—

Flavazine	1 oz.
Water	10 ozs.

in which the screen, previously coated with gelatine, is immersed until it obtains the required colour density.

After the film has been exposed, it is developed in the ordinary way, and a positive is prepared therefrom. The alternate exposures are then coloured as already described. The coloured film can then be projected from an ordinary cinematograph apparatus.

For colouring, the following solutions are preferred:—

For the blue-green positive:—

Victoria blue	¼ oz.
Patent blue	¼ oz.
Naphthol green	½ oz.
Water	10 ozs.

For the orange-pink positive:—

Rose bengal	½ oz.
Flavazine	½ oz.
Water	10 ozs.

Instead, however, of colouring the film itself, a black and white positive film can be projected from a cinematograph apparatus fitted with a revolving tinted screen, approximately one-half of which is coloured orange-pink and the other portion blue-green, so that the pictures are projected through the colours.

It is to be understood that the revolving disc, provided with a slit and coloured, may be used in place of the usual shutter, the portion of the disc between the slit and the colouring being blackened or otherwise rendered opaque.

AUTUMN FOLIAGE BY THE SCREEN-PLATE PROCESSES.

The brilliantly tinted foliage of various shades inseparable from late autumn have always held a distinct attraction for the photographer, and more particularly for the colour photographer, who looks upon his medium as a means of recording these transient beauties, accurately in permanent form, as colour transparencies. That this is as it should be is amply borne out by the fact that many of the most successful landscape colour transparencies represent autumn subjects. There are, however, some points having a special bearing upon colour photography by the screen-plate processes that are evidently often overlooked by the majority of photographers.

Many colour photographers by the screen-plate processes, when making a first attempt at a rendering of autumn tints, often make the mistake of including too large an area of the subject upon the plate, particularly if the finished transparency is intended for viewing in the hand, and not for lantern projection, in which case a much wider expanse of subject may be included, owing to the fact that the picture is seen upon a much larger scale. In the former case, an expanse of woodland, while very attractive to the eye, is not to be regarded as an ideal subject for colour photography, for in reason the smaller the area included by the lens, and the larger the scale upon which the subject is rendered, the better. A group of two or three beech boles, well placed upon the plate, with a carpet of fallen brown or red leaves, interspersed with patches of green moss, and the rich yellows, reds and browns of the foliage, is often more effective, from the pictorial point of view, than one in which the subject is far wider in area and more varied and interesting. One of the greatest difficulties in selecting a subject for colour photography may be said to lie in a full realisation of what will make a fine colour photograph, as distinct from what has naturally, by reason of its wider extent, a greater appeal to the human eye. The truism that the part is often greater than the whole is applicable to colour photography, to an even greater extent than when the subject is rendered in monochrome.

The next point is that the colours should contrast. For instance, it is possible to select a composition consisting almost entirely of a beautiful shade of yellow. This will only look monotonous, but if the yellow tint can be broken up, as it were, and balanced with brown or red, or even green, a pleasing composition may be produced. The ordinary summer landscape, for instance, formed almost entirely of greens, is for this very reason inclined to be uninteresting, unless a small amount of another colour or colours can be introduced, such as flowers or human figures, wearing light or distinctive clothing, or even the red brickwork of buildings, that serve to break up the monotony. In the same way autumn tints should be as varied as possible, and in this respect the ideal subject needs only a little seeking by the thoughtful worker.

Contrast in the matter of lighting is also one of the problems of autumn landscape photography in colours. Many workers are inclined to neglect the study of this, to the detriment of their results. As is well known, the screen-plate colour processes cannot give a very perfect rendering of very deep shadows and very brilliant high-lights with the same exposure. In most autumn photography under trees and in the woods the finest combinations of colours are usually to be found, where the inequality of the lighting is a factor that demands special consideration. Some photographers, when attempting woodland photography in the natural colours of the subject, seek to obtain pictures in naturally isolated surroundings that will allow of the production of a perfect technical result without seeking to overcome the difficulties that arise when extremes of contrast in the lighting are in evidence. The results in the former case, though accurate enough from the scientific point of view, often leave much to be desired in the matter of pictorial qualities, and the matter of obtaining a good transparency from subjects differing widely in their lighting contrasts is not one that is to be shirked in this way if the worker really wishes to produce something worth while.

In illustration of this I may mention an experience of my own. Only last autumn I was photographing upon Autochrome plates the beautiful tints and colour contrasts of a certain stretch of woodland near my home. In the course of the day I came upon a most beautiful colour composition, both from the point of view of contrast and balance of the colours. The lighting, however, was the problem. Shafts of mellow sunlight striking down through the half bare boughs of adjacent trees lit the golden yellow foliage of a giant beech to perfection and also picked out in rich brilliance the reddish brown of the fallen leaves upon the near foreground. From the scientific point of view the subject was one impossible to transcribe into a perfect Autochrome. The background, consisting of holly and fir trees, received hardly any light at all, while the brief exposure needed, to secure a good rendering of the upper boughs of the beech, would allow of no detail in the foreground, which was, of course, less well lighted. Determining to make the best of things, an exposure was made, after a careful meter test, which, from what I remember, overexposed the lightest part of the picture fully six times, while it left the "second lights," if the term may be coined for the purposes of description, slightly under-exposed, while, of course, the deep shadows were grossly under-exposed. I should

mention, however, that when composing the picture the camera was so directed that as little of the darker background was included as possible. This is a most useful dodge, and may, with a little manœuvring, allow of a presentable rendering of many a subject that might otherwise have to be passed by. The plate was developed with the usual tabloid "Rytol" developer, at the same strength and for the same time as indicated in "The Wellcome Photographic Exposure Record and Diary." After the second development it was found that the transparency, though satisfactory as regards the foreground, was rather weak in the high-lights through very considerable local over-exposure. The plate was then intensified by the chromium method, the result being a transparency of very fair quality. I need only add that it received an award at a large provincial photographic exhibition this last spring. I would advise those who are attempting Autochrome work upon the changing foliage of this autumn not to avoid entirely subjects having fairly great extremes of contrast, but rather to try the effect of a carefully calculated exposure, trusting what latitude in the matter of exposure the Autochrome plate possesses, which is more than some colour workers would have us believe. The point to be noted is, that it is possible to compromise in the matter of the exposure required for subjects where the contrasts of the lighting are not too great and still obtain a very fine result, always provided this is effected without any undue *lack* of the required exposure in the more important of the shadows. This may sound a rather unscientific doctrine, but in practice there are cases where it is worth while following it out rather than pass by an otherwise fine colour subject. One other point may be profitably mentioned, more in the light of a warning. Autumn tints in this country are very transient, and at their best may be looked upon to last only a few days if the weather conditions favour this; while if this is not the case, the foliage may be at its finest only for a matter of a few hours. Many workers make the mistake of making the exposure *before* the foliage assumes its richest colours, while others are inclined to take up too much time in thinking about the suitability of time or subject, so that when they do finally make up their minds the leaves have fallen and the boughs bare, for the finest colours are only taken on by the leaves just before they fall. Another factor that often tends to add to the colour photographer's difficulties is the strong wind that so often accompanies the bright days of late autumn, though if a sheltered wood is chosen any ill-effects that this might have upon the details of the subject while the exposures are being made may be greatly minimised. For my own part, I would advise that, if wind is troublesome, the exposures be deferred to another day; the only result likely is that of wasted plates, since a satisfactory transparency of autumn foliage demands the maximum sharpness of definition.

ROBERT M. FANSTONE.

THE GORSKY PROCESS OF COLOUR CINEMATOGRAPHY.

[A recent patent specification, No. 168,100, describes the method of preparing three-colour films for cinematograph projection, which presumably forms the basis of the system of preparing ready-to-show cinema films which is being worked out in this country by Professor de Procoudine-Gorsky. As will be seen from the following extracts from the specification the process chiefly consists in the production of superimposed colour impressions of yellow, red and blue colours, the two former by a process of dye-mordanting and the latter by chemical toning.—EDS. "Colour Photography" Supplement.]

THIS invention is more particularly applicable to and will be described with reference to the process in which a cinematograph negative is taken through a recurring set of colour filters thereby obtaining a recurring series of colour-record negatives on one film. The three positives are produced by printing in turn from the three different series of colour records, and in printing each positive, the negative is stepped the extent of three pictures at each shift.

The invention primarily consists in a process for the production of such fully coloured positive images from the corresponding negatives, in which the positive images from the negatives of violet-blue sensation are coloured yellow by means of a solution of basic auramine in the presence of basic aluminium acetate, the presence of the latter distinguishing the process from prior processes in which auramine is used either in the presence of acetic acid or in other ways.

The invention further consists in a process as set forth in the preceding paragraph in which the positive images from the negative of green sensation are coloured red by means of a solution of rhodamine in the presence of acetic acid, and the positive images from the negative images of yellow sensation are toned or coloured blue by means of a solution of potassium ferricyanide and ammonia immersed in solutions of ferric chloride and sodium thiosulphate, and finally in sulphuric acid.

The invention also consists in a process as set forth in the two preceding paragraphs, in which the respective negative images have been taken through light-filters of methyl violet 6B, brilliant green and Bengal rose, the ultra violet rays being eliminated.

The invention also consists in a process as set forth in the three preceding paragraphs, in which the use of a protective stratum between the component positives is avoided by treating the layer of gelatine bearing the image with a hardening solution, well washing, and then coating the next layer of sensitive emulsion without drying.

In carrying the invention into effect, a negative emulsion is panchromatised by treatment with ethyl red in the manner described by Professor Miethe, in order to obtain an emulsion having a practical equality of sensitivity to the red, orange, yellow and green rays of the solar spectrum. The negative emulsion (that is, the negative film) is exposed by means of a cinematograph camera fitted with the requisite light-filters, and capable of working at a speed of forty-eight or more pictures per second for prolonged periods. The three light-filters are carefully chosen, and are preferably of methyl violet 6B, brilliant green, and Bengal rose. The first light-filter passes all the red, orange and yellow rays; the second, all rays having a wave length of 500—600$\mu\mu$, that is, the green part of the spectrum, the third light-filter passes the rest of the solar spectrum, that is, the blue, indigo and violet rays, and also the ultra-violet rays.

A sufficient quantity of tartrazine is added to the Bengal rose and brilliant green filters to absorb the blue, indigo and violet rays. An aesculine screen is used in conjunction with the methyl violet 6B filter, in order to absorb the ultra-violet rays. The aesculine, however, must be very pure, and be of the kind produced by Dr. E. König.

The exposed negative film is developed, fixed, and washed, after which a positive is made in the following manner:—From the negative film the pictures first printed upon the positive film are those exposed through the violet blue light-filter. The printing machine is adapted in such manner that the print of every successive image of like colour-sensation on the negative film, which is separated by images of other colour-

sensations, is printed on the positive film in a contiguous and successive series of images of like colour-sensations. When the positive film has received images of like colour sensation, has been developed in the usual manner, and dried, it has to be of the complementary colour to the light-filter through which the negative image was taken. That is to say, the positive images from negatives exposed under the violet-blue filter must be coloured yellow; those positive images from negatives exposed under the red or orange filter must be coloured blue, and those positive images from negatives exposed under the green filter must be coloured red.

In the present instance the positive image of violet-blue colour-sensation having been made first, the positive film is to be coloured yellow. It is immersed in a solution of potassium ferricyanide to which has been added a solution of potassium iodide and ammonium hydrate. Upon immersion in this solution the metallic silver of the image is converted partly into silver iodide and partly into silver ferrocyanide. About three minutes is the average time required for this operation. The film is now washed for about five minutes in running water, and then dipped into a solution of basic auramine in the presence of acetic acid and basic aluminium acetate. The solution of the latter salt should be freshly prepared as it is of the greatest importance for the purpose of obtaining a lake-like substance. Basic auramine if used in the manner already described does not lose depth of tone in colour when being washed, and gives a correct colour rendering. The use of this dye in the foregoing manner involves the formation of a lake-like substance formed by the action of basic auramine on silver iodide and silver ferrocyanide, which is "fixed" in the presence of basic aluminium acetate. The process takes about five to eight minutes, according to the density of the image.

By means of a second washing in running water the superfluous dye is removed, while the greater part of the silver iodide becomes transformed into a lake-like substance; but experience shows that in this process a certain part of the silver iodide remains unchanged, causing an opalescence of the image and does not enter into the formation of the lake-like substance. For the purpose of the present invention all clear parts of the gelatine should be absolutely transparent, and the dye used must be totally removed by the washing. The positive film is further washed in a solution of tannin and glycerine, whereby the whole gelatine coating is tanned by the tannin and the glycerine renders the layer supple, the latter being of importance during the subsequent manipulation of the film. The operation takes about five minutes. The positive film is then transferred into a fixing solution, which removes the small remaining quantity of silver iodide which is not converted into a lake-like substance, and makes the film absolutely transparent; the image remaining a golden yellow colour. The fixing solution comprises sodium thiosulphate in the presence of some of the tanning solution (that which adheres to the film), as experience shows that the presence of the latter solution causes the fixing to proceed more equally. The film is now washed and dried.

The coloured positive image may now be hardened by treatment with potash alum, chrome alum, formaline or other hardening solutions, well washed to eliminate the hardening solution, and coated directly with the next sensitive emulsion without the drying of the treated gelatine coating, but it is very important that the hardening substance should be washed away as far as possible so that it may not have any influence on the lake-like substance of the image or the following coatings of the sensitive emulsion. Alternatively the emulsion may be covered with a gelatine solution to which has been added a small proportion of a hardening solution, dried, and then coated with the next layer of emulsion. If desired, however, the coloured positive film may be protected when necessary from any subsequent chemical manipulations by coating the emulsion side with a protective stratum comprising a very thin but solid layer of a 1 per cent. solution of rubber in benzol. Following this, the emulsion side of the positive film is coated with a solution of celluloid in acetone. A very thin layer which resists any of the applied solutions may be obtained by spraying the solutions on to the positive film by means of an aerograph. When a protective stratum is used it has been found absolutely necessary to use coatings of both solutions, as if only one of them is applied the coating is permeable even in thick layers.

Following the protection or hardening of the yellow coloured positive images, the positive film is now coated on the same side by machinery with a positive emulsion containing a sufficient quantity of silver bromide for the formation of a lake-like coloured image. The negative images taken through the green light-filter are now printed upon the positive film by means of a printing machine adapted as already described. The manipulation of the positive film is now similar to that described with reference to the positive images printed from the negatives of violet-blue colour sensation, the difference being that rhodamine is used in the presence of acetic acid to obtain the red coloured component.

The printing of the negative images taken through the Bengal rose filter is the last printing operation to be carried out by the printing machine, the impression of the images being made upon the coating of the positive emulsion directly coated upon the hardened red coloured images, or upon a coating isolated therefrom by means of a protective stratum. The images so obtained are then coloured or toned blue by a solution of potassium ferricyanide and ammonia, washed in running water, immersed in a solution of ferric chloride, immersed in a solution of sodium thiosulphate and finally immersed in dilute sulphuric acid. After washing and drying, the positive film receives a final protective coating of rubber and celluloid.

From the foregoing it will be observed that the present process affords an exceedingly thin and transparent film which does not scale under the action of heat, and which may be projected on to the screen from standard cinematograph apparatus at the normal speed of 16 pictures per second.

TWO-COLOUR STUDIO PORTRAITS.

WHILE experimental work in colour photography during the last few years has centred chiefly in colour cinematography, it is interesting to find that the application of methods to the making of portraits in the studio is not being neglected. In the "Colour Photography" Supplement of June last we published extracts from a patent specification describing a method of preparing a component image for a colour process by toning with uranium in conjunction with the addition of a certain red dye to the toning solution. Within the last few days we have had the opportunity of seeing examples of this process (a two-colour one) which has been perfected by Mr. J. Newlands Thomson, of 22, Brook Street, London, W. In this process two negatives are made of the sitter, one through a blue-violet screen on an ordinary plate and the other through a specially prepared red filter on a panchromatic plate. From the former a positive transparency is made on a stripping plate. The transparency is toned in the special uranium toning solution in the ordinary manner, yielding an image which is of the reddish-brown colour familiar in the uranium toning process. From the red filter negative a bromide print is made and is toned to a blue by means of a mixture of ferricyanide and ferric ammonium citrate. The two-colour photograph is produced by stripping the reddish image from the transparency plate on to the blue-toned bromide print. It will be seen that the process thus allows of the final colour effect being very fairly gauged, before effecting the combination of the two components, by laying the glass transparency upon the bromide print.

Although it is not claimed for the process that it provides, or can provide, a facsimile rendering of a wide range of colours, and especially of brilliant colours, we were interested in observing the very great degree of success with which complexion tints and the colour of hair are rendered. From a demonstration kindly given to us by Mr. Thomson, it was clear that so far as the manipulation is concerned the process presents no difficulties, and the fact that for a considerable time past portraits made by it have been regularly supplied to sitters by this West-End firm is sufficient evidence of its practicability and of the pleasing character of the results yielded

by it. Mr. Thomson, like other experimenters in colour photography applied to portraiture, does not disguise from himself the fact that sitters frequently wish for a colour rendering which is a distinct variation from a truthful one, and that a colour portrait process does not exclude the employment of a certain degree of hand-colouring of the prints. Most of the portraits are, in fact, finished by hand in the same way as an ordinary photograph is finished, except that on the colour print colour dyes are used, whereas on an ordinary print Indian ink would be used. The cost of production is low, and the commercial possibilities of the process are certainly considerable.

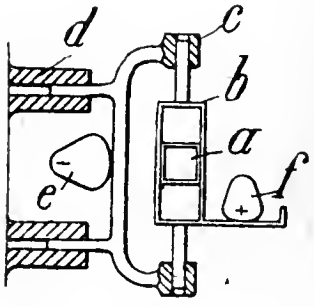
THE ULYSSE PROCESS OF COLOUR-CINEMATOGRAPHY.

A process of cinematography in natural colours devised by M. Pierre Ulysse, Le Val-Pre, Saint-Loup, near Marseilles, is described in Patent No. 100,021.

Each picture area receives several partial exposures through the same colour filter at different times.

By way of example, a known method will be considered in which three selected images are successively taken on three separate parts of a picture space of standard size—namely, 1 in. × ¾ in.—through red, green and blue-violet filters by means of a mechanism which moves the film through three successive exposure-positions at each pause in the unwinding movement of the film, and giving the whole of the desired exposure at each of the three positions.

As modified by the invention, this method consists in causing the film to move through the three exposure positions, not once in each pause in the unwinding movement as hitherto, but several times—for example, four times—giving an exposure at each position which is, for example, one-quarter of the desired total time



Thereby each selected image is made up of four partial exposures, on the same small picture-area of the film, made at slightly different times.

It has been found that by this improved method undesirable colour-fringing and discontinuity of impression in the images projected on the screen are minimised.

The apparatus to be used for producing the movements between the film and the lens may be similar to those which have been proposed hitherto in colour cinematography of the kind mentioned above, with the difference that means are provided for causing the movements to be repeated a number of times, instead of once only, in each pause in the unwinding movement of the film.

The drawing shows diagrammatically such an apparatus, adapted to produce three selected images grouped on the space usually occupied by a monochrome image of standard size, the centres of the three images being at the corners of an isosceles triangle. The gate *a* is mounted in a frame *b* which can slide vertically in a second frame *c* mounted in guides to slide horizontally in the plane of the film. Cams *e* and *f* produce horizontal and vertical motions of the gate *a* in timed relationship to the lens shutter so as to produce the three selected images in succession, and a separate film advancing device (not shown) is employed for the unwinding movement of the film. Instead of the cams *e* and *f* performing only one cycle of movements in each pause in the unwinding movement, they are geared to perform several complete cycles in each pause—for example four cycles.

The invention is, of course, not limited to the particular form wherein the film-gate is moved to produce the successive exposures, as the same effect may be produced in other ways, for example, by interposing a movable mirror device between the lens and the film.

News and Notes.

The Loudine Colour Process.—A recent issue of "Photographische Industrie" contains a brief note on the Loudine colour process, for which, in the years immediately preceding the war, great things were occasionally prophesied. It is stated that Herr Loudine has established a research firm for the development of his process, particularly in application to films. A large film studio in Geiselga Steig, Munich, has attached to it his experimental laboratory. A former collaborator with him has given some few details of the process, but only to the extent of stating that a negative is made in complementary colours and permits of either prints or transparencies being produced in any required number by a process almost as simple as ordinary photography. It is further intimated that the colour quality of the results are immensely superior to anything hitherto shown. The writer in "Photographische Industrie" has had no means of confirming these claims, but he reposes great confidence in his informant, and, therefore, sees no reason to doubt that we are on the verge of a great turning-point in the history of photography. The editor of "Photographische Industrie," however, makes the excellent suggestion that some technical information with regard to the process should be published.

The Modern Craze for Colour.—The growing craze for colour should please those workers in colour photography who complain about the "dullness" of our natural scenery and our home interiors. As a writer in the "Star" a few days ago said, we English people seem to be crazy on colour these days—in our clothes and our houses, at any rate. Now even our gardens have not enough colour apparently, and even the paths must receive attention, as well as the beds. When stones are used, grey paving is no longer considered all-sufficient, for paving stones can now be bought in almost any colour—white, brown, red, slate blue, even green and mauve—and laid in any size and shape, large or small. It adds to the work, however, for it requires constant washing if the colour is not to be obscured.

"Are you one of those people (asks the "Star" writer) who love good pictures, and, being unable to afford them, find the ones you possess a continual eyesore? If so, try making the wall-paper the principal feature in one of your rooms, and do away with pictures altogether. A paper with a black ground and a many-coloured pattern requires no pictures; indeed, they would quite spoil the effect. Even ornaments are not in the scheme, though a very few plain silver bowls and vases on the mantelpiece look extremely well."

Screen-plate Renderings of Fashionable Complexions.—Those workers who are not pleased with the screen-plate renderings of normal flesh tones, or who are unable to manipulate the plates so successfully as to secure pleasing renderings of the human face, will no doubt welcome the latest fashionable fad, which originated a week or so ago at Deauville, namely, that of powdering the face of a colour to match and be in harmony with the hat or frock. It may be only a passing fad it is true, but it is one that brings grist to the colour photographer's mill, and as such is worthy of some attention. According to a fashionable expert (a lady) from Deauville, who was button-holed by a representative of the "Daily Chronicle," the popularity of scarlet hats and gowns accounted for the new colour-schemes for faces. "It is obvious," she said, "that the mauve face powder, which many women cling to, looks dreadful with a red dress. A clever woman, who liked red frocks had," she said, "experimented with powders, and found how very much better powder with a red tinge looked than a neutral or mauve-tinted one. Smart women were, therefore, ordering powder with a peculiar mauve tint for their dresses of the fashionable mauve colourings, red-shaded powders for their red dresses, and blue powder for use with blue dresses."

COLOUR REGISTRATION DEVICES IN THE PAGET PROCESS.

[We reprint below the major portion of the recent patent specification No. 167,793 of Mr. G. Sydney Whitfield, describing a device for use in an extension of the Paget colour process, which actually is very simple in practice, although forbiddingly complex when set down in the language of the professional draughtsman of patent specifications. It will be seen that by providing supplementary colour patches of adjusted transmission on the taking screen the user of the process obtains a colour indication of correct register when employing a key screen for the purpose of making a set of three colour-sensation negatives.—Eds. "Colour Photography" Supplement.]

In the method of producing photographic prints in natural colours from a "screen plate negative," such as, for instance, one taken through a Paget taking screen, a stop-out or key screen is used, placed in correct register upon the negative so that only the record of one element of the colour screen is used at a time for the purpose of making a print for subsequent use in complementary colour in the composition of a colour print. It is a difficult matter to know when the key screen is in correct register with the screen plate negative to permit only one colour record to appear at a time, and in order to ensure correct registration, without any doubt whatever, it is found advisable to provide on a part of the taking screen a registering device that will be recorded on the negative and to provide a corresponding device on the key screen in such a manner that when the registering device on the key screen is in register with the recorded registering device on the negative, it is assured that the key screen is in correct position on the picture portion of the negative, and is allowing only the colour record of one of the taking screen elements to be available.

Now, as the colour recording negative is of the usual black silver compound and the key screen is in a similar black and white condition, there is great uncertainty, even with the aid of the above-mentioned registering devices, in knowing when the key screen is in exact register with the negative, as the eye cannot (owing to the whole of the registering devices on the colour recording negative and key screen being in a neutral grey of varying intensities) readily perceive slight variations of register when the relative positions of the key screen and negative plate are changed. The object of the invention is to overcome this difficulty.

For this purpose there is employed a key screen having the registering means in certain colours such that when registering it with a colour record negative having registering means thereon produced by the aid of a taking screen having coloured registering means thereon, preparatory to printing a positive, the registering means on the key screen will be seen in a predetermined colour only when the key screen and negative are in exact register, whilst any want of exact register will at once be rendered apparent by an appearance of colour other than that which indicates correct register and can be corrected by relative adjustment of the key screen and negative.

The accompanying drawings show one example of the application of the method of registering when used with the well-known Paget colour process.

In these drawings, fig. 1 represents in face view part of a Paget taking screen embodying the invention. Figs. 2 and 3, shown in vertical section on lines corresponding to lines A A

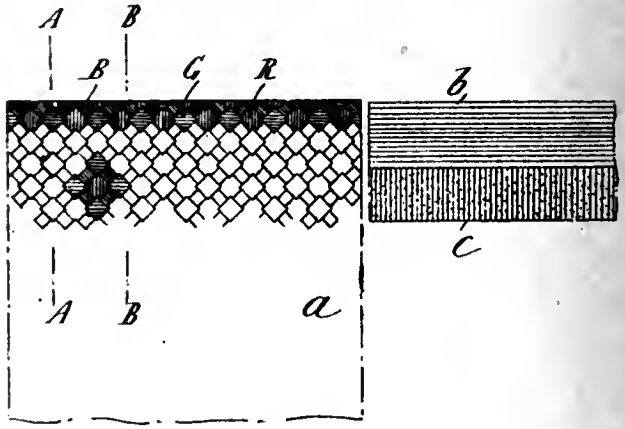

Fig. 1.

and B B respectively of fig. 1, portions of a negative plate and of the taking screen, with a registering device as described below, superposed and exposed. Fig. 4 shows in face view a portion of the negative obtained by such exposure. Figs. 5 and 6 are face views of portions of two key screens embodying the invention. Figs. 7 and 8 show in vertical section portions of the negative plate and the key screen shown in fig. 5, superposed and in different relative positions for registering in two different colours. Fig. 9 is a similar view to figs. 7 and 8, but showing the negative plate with the key screen shown in fig. 6 superposed.

In the Paget taking screen the three-colour pattern usually consists of a series of coloured squares, the red and green

elements, marked respectively R and G, being of the same dimensions, whilst the blue elements, marked B, are of smaller dimensions, the several elements being symmetrically arranged as in the example shown in fig. 1. For distinction, the red squares R are denoted by vertical lines, the green squares G by horizontal lines, and the blue squares B by diagonal lines. In the drawings, the squares constituting the pattern in the taking screen and key screens and the negative are, for the sake of clearness, greatly enlarged.

At opposite ends of the Paget taking screen *a* and on top of the three-colour pattern thereon are placed at each end

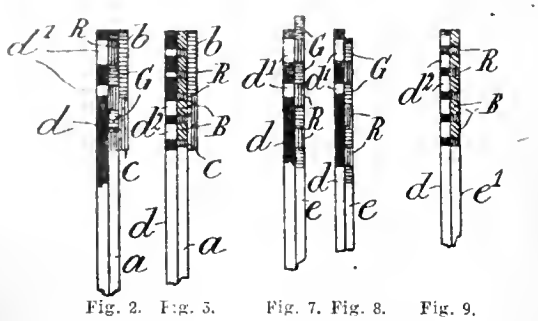

Fig. 2. Fig. 3. Fig. 7. Fig. 8. Fig. 9.

two continuous transparent strips of different colour, indicated for clearness at *b* and *c* to one side of the screen, such colours being those that will transmit, in each case, the light passed by two only of the colour elements of the taking screen, and such that one of the colours transmitted by one strip shall not be transmitted by the other strip. For instance, one of the strips, say *b*, may be a greenish-blue strip, which will enable only the light transmitted by the green and blue-violet elements G and B of the taking screen *a* to be recorded on a negative, and the second strip *c* may be yellow, which will enable only the light transmitted through the red and green elements R and G of the screen to be recorded on the negative. When a negative is taken on a panchromatic plate *d* through such a taking screen and suitable precautions are taken so that the two end portions of the colour screen *a* having the colour strips *b* and *c* thereon receive adequate exposure, a pattern will be produced on each end of the negative (fig. 4), consisting, in the case of the greenish blue strip *b* (fig. 2), of opacity behind the position occupied by the

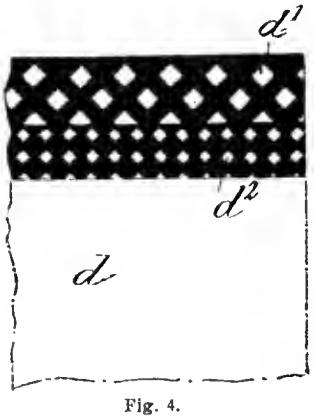

Fig. 4.

green and blue violet elements G and B of the screen *a*, but clear open pattern at d^1 behind the position of the red elements R of the screen. In the case of the yellow strip *c* (fig. 3), there will be produced on the end portions of the negative, as shown in fig. 4, opacity behind the position occupied by the red and green elements R and G of the screen, but open pattern at d^2 behind the positions of the blue violet elements B of the screen.

The key screen *e* (fig. 5) may be of the usual black and white pattern *f* and *g* respectively, suitable to block out the negative colour record of any two of the colour elements of the taking screen *a*, whilst transmitting fully the remaining negative colour record of such taking screen in such gradations as the negative may possess, but at each of its two opposite ends the black and white pattern *f* and *g* is replaced, as shown, by a strip *h* of colour screen identical with that on the Paget taking screen *a* (fig. 1), used in preparing the negative, these two strips *h* of colour screen being arranged in correct relationship with the black and white portion *f* and *g* of the key screen.

On such a key screen *e*, constructed as shown in fig. 5, being placed, as shown in fig. 7, in register with a negative *d* (fig. 4) taken under the above conditions, that is to say, with a taking screen provided at each end with colour registering means *b* and *c* as described, it will be found that those end portions of the negative *d* corresponding to or representing the greenish blue strips *b*, can, by suitable adjustment of the negative relatively to the key screen, be registered at both ends to cause the red elements R of the colour screen *h* on the key screen *e* to come exactly opposite the clear portions d^1 of the negative (fig. 7), thus giving a bright red effect, indicating that the red element record only in the negative is then available for use, and a positive made from it will form the blue element of a tri-colour print.

If the same end portions of the negative *d* corresponding to the greenish blue strips *b*, by relative adjustment of the

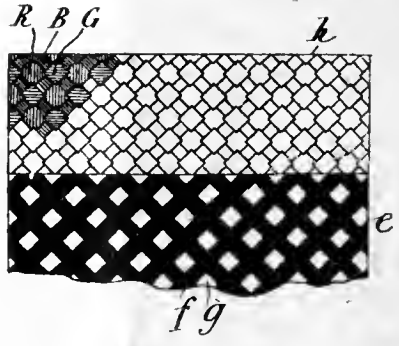

Fig. 5.

key screen and negative, be registered at both ends to cause the green elements G of the colour screen *h* on each end of the key screen to come opposite the clear portions d^1 of the negative *d*, as shown in fig. 8, a bright green effect will be obtained, thus indicating that the green element record is capable of being used, and the resulting positive will form the magenta element of the tri-colour print. Similarly, if the end portions of the negative representing the yellow strips *c* of the taking screen can be accurately registered with the colour screen edge portions *h* of the key screen used so that these portions will give in like manner an even blue tint when the blue elements B of such portions come opposite the clear portions d^2 of the negative, it will prove that the negative is in the correct position to give the positive for the yellow element of the tri-colour print.

One key screen would suffice for making, in the manner above described, three positives of the three-colour record on the negative, if the three-colour elements of the taking screen used for producing such negative were of the same size and shape and symmetrically arranged, so that the key screen would only have to be shifted to block out any two of the colours at each adjustment. Should, however, the size and shape of the three-colour elements of the taking screen differ from each other, two or more key screens of pattern, size and edging suitable to the elements concerned must be used. Thus, when using the Paget taking screen *a* shown in fig. 1 to produce the negative, one key screen *e*, such as shown in fig. 5, will suffice for dealing with both the red and green records of equal size on the resulting negative, but a different key screen e^1, such as shown in fig. 6, corresponding to the smaller blue elements B of the ordinary Paget taking screen, must

be used for dealing with the blue record. In this case, the screen e^1 must be moved endways relatively to the negative d to bring the blue elements B of the colour screen h thereon accurately opposite the clear portions d^2 of the negative, as shown in fig. 9, thus indicating that the blue elements record only in the negative is available for use, and a positive made

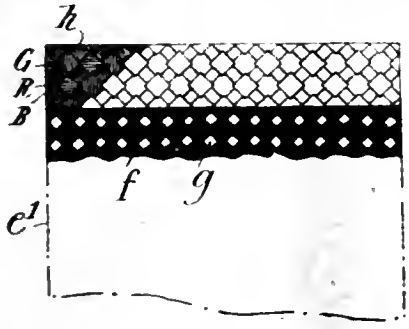

Fig. 6.

from it will serve for the yellow element of the tri-colour print. However many key screens may have to be used, they are all provided with a colour screen edge portion h of a pattern similar to that of the taking screen used.

It will be understood from the above that when, for instance, the red screen element record on the negative is being used and the colour record strips at the edges of the negative and key screen are being registered to an even and complete red, any error of registration will at once be shown by the appearance of a portion of either green or blue violet, and the register may be re-adjusted until the latter colours are entirely removed. Likewise, any appearance of red, when the strips are being registered to a green, would at once be recognised as indicating faulty registration, and must be immediately corrected. The same remarks apply when the strips are being registered to a blue.

The portion of the key screen described as black and white may be of any other character, such as red and white, always providing that the colour used does not transmit light of such a nature that the material used in making the positives will be affected by it.

Instead of providing each end portion of a taking screen a with two differently coloured strips b and c, such as described, one edge portion only may be so provided, and one end portion only of a key screen e or e^1 may be provided with a strip of colour screen h such as described. As will readily be understood, accurate results cannot, however, be so easily attained in these cases as when each end portion of a taking screen and of a key screen are constructed as described, which is therefore the preferred construction.

THREE-COLOUR REFLECTOR CAMERAS.

The only methods at present available for producing natural colour photographs on paper are founded on the three-colour principle, and each finished picture represents the combined effect of three printings, i.e., pink, blue and yellow, the prints being derived from separate negatives taken through complementary colour filters. Usually these three negatives are taken as rapidly as possible one after the other. The disadvantages of this method of taking are obvious. For instance, the light may change, due to passing clouds, or usually the subject moves and the picture is ruined by brilliant colour fringes. In addition, it is not easy to get the relative exposures of the negatives correct. There is far less latitude in three-colour work than in monochrome; in fact, Abney[1] states that exposures should be correct within 2 per cent. Provided, however, that a perfect set of negatives has been obtained, the production of a real natural-colour photograph is not beyond the technique of a good, average photographer. Colour photography would, therefore, receive an immense impetus if a camera were available that could take these three negatives simultaneously with one lens and with the same ease that a monochrome image is obtained. The principal requirements of such a camera are:—

(1) Three images identical in size.
(2) Correct colour separation for each negative.
(3) Relative exposure ratio correct.
(4) Modern lenses giving high speed and diffusion of focus if required should be fitted.
(5) Portability.

The most promising type of camera to fulfil these requirements appears to be one embodying semi-transparent reflectors, which partly transmit and partly reflect the image-forming rays of light. I believe I am correct in saying that Ducos du Hauron was the first to employ this principle, and his reflectors were plain sheets of glass. It is a well-known fact that such reflectors give a double image, and du Hauron was forced to use long-focus lenses, including only a very narrow angle of view. Ives rendered such cameras practicable by employing reflectors of a colour complementary to the reflected image. Thus a greenish-blue reflector might transmit the necessary light to the blue- and green-filter negatives, and its secondary image would be damped out by the red filter. There are three interesting early patents in connection with this type of camera, viz.:—

(1) No. 8,663 of 1896, granted to Walter White.
(2) No. 28,920 of 1897, granted to J. W. Bennetto.
(3) No. 29,353 of 1897, granted to E. T. Butler.

Bennetto's camera had a single red reflector at 45 deg. to the lens axis, the first reflected image falling on two plates, placed face to face. I saw some very extraordinary results obtained by this camera, but the Polychromide camera, on a somewhat similar principle, was infinitely more successful. Incorporated in this camera is rather a curious patent by A. Hamburger, whereby registration is more perfectly obtained by bending the transparent reflector.

Butler's camera is pretty well known, and has two parallel semi-transparent reflectors. These are, of course, coloured to damp out secondary images, as previously explained. In a camera, of which I have a half share, the direct and brightest image is arranged to fall on the green-filter plate, the first reflected image is for the red plate, the second reflected image is blue. The principal difficulty in a reflector camera is that the ratio $\frac{\text{light reflected}}{\text{light transmitted}}$ varies with the angle at which the rays fall on the reflector. The direct and second reflected negatives are apt to be graded in intensity from top to bottom. Mr. Butler corrects this with internal diaphragms in the camera. For the same reason a comparatively long-focus lens is desirable.

I believe, however, that the most successful arrangement of reflectors is that contained in White's patent before mentioned and shown in the accompanying figure. I have good reason to suppose that I have the original model of this camera, which I picked up for a mere song in a pawn-

[1] "Instruction in Photography," 1905 Ed., page 435.

shap As I found it, the colours of the reflectors and light-filters in my model are exactly the same as given in "Photography in Colours."[2]

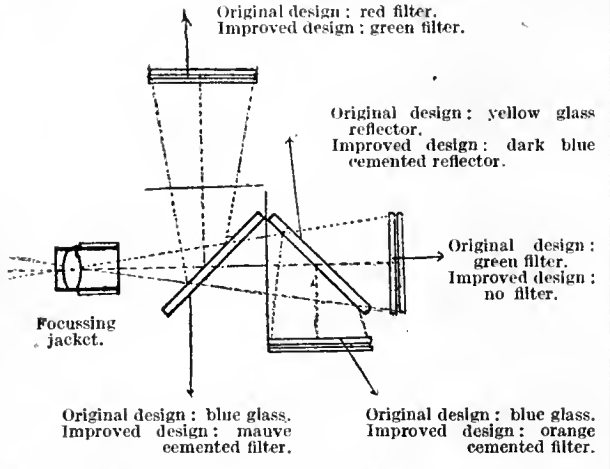
The camera is a curious example of the freakishness of the human mind, which in this case must have lavished quite a considerable sum on a construction which was inherently sound, but which failed owing to a lack of knowledge on the part of the designer. The great advantage of this reflector arrangement is that the tendency to uneven lighting in the direct and second reflected images is exactly corrected by having the reflectors at right-angles. None of my negatives show the least trace of it.

I have spent some time and trouble in adjusting it to work satisfactorily, using the following system of colour filters :—

First reflector, mauve, transmitting red and blue.
First reflected image, green filter.
Second reflector, dark blue.
Second reflected image, red. An orange filter is used as shown.
Direct image, blue filter.

I have adopted really heavy cemented filters, which were made by Messrs. Kodak, Ltd., the glass for the reflectors being specially selected.

The method of adjusting the camera is to focus the direct image, set the reflectors accurately at 45 deg., shift them nearer to or more remote from their respective plates until they give sharply-defined images. The first exposure is made on some symmetrical diagram of lines and circles. Each reflector negative is placed face to face with the direct negative, and it is simple to define in what way the reflected image is distorted. If one corner is expanded it shows that the



Diagrammatic sketch of White's camera in original and improved form.

corresponding corner of the reflector producing that image is too distant from that plate, and *vice versâ*. By a similar reasoning a "long" or a "wide" image may be corrected.

The next problem to be dealt with is equalising the exposures to each plate, and this is done by a film compensating filter in the lens. In my case an Autochrome filter seems to balance the system almost exactly, and I can always develop the three plates simultaneously.

There were two reasons for having the blue image the direct one, the first being that I could make a yellow Raydex print direct on paper and register the pink and blue on it, thus obtaining a finished print with only two transfers; secondly, I wished to have a camera equally suitable for artificial light, in which case the balance filter can be removed, giving the blue plate a very full exposure.

The blue reflector is a very dark blue, cutting out the ultra-violet entirely and some of the visual violet. This is done to avoid the flatness and dullness which is often characteristic of the yellow printing plate. I am so pleased with the results obtained that I advise other three-colour workers to give this filter (Wratten C4 dark) a trial.

With this camera a brightly-lit seascape requires 1 second at *f*/11, and a portrait on a dull day, with the same stop, 12 seconds. I usually use an exposure meter, the speed being estimated at 10 Watkins.

In my experiments with reflector cameras I have had many discouragements and disappointments, nearly leading me to abandon them. I am now convinced that the system outlined above is as near perfection as can be, giving three good clear negatives at one exposure. For portraiture each negative can be retouched. In fact, this usually has to be done to get correct colour rendering, due to the imperfections of the pigments used. I do not think professional photographers would have the least difficulty over this part of the process. The essentials for success in this type of camera appear to be :—

(1) Good solid reflectors of carefully selected glass, with cemented gelatine filters.

(2) Correct design. The thickness of the colour-filters and their refractive indices for the various regions of the spectrum have to be taken into consideration to get the images equal. The focus of the lens used, for red, green, and blue rays, also has to be measured. Mr. Butler informs me that he can adjust his cameras, even for uncorrected lenses.

(3) Rigid construction. A good solid box form must be adopted. I do not think it possible to have any folding construction. Reflectors must be rigidly held down, and if they are thick enough there is no fear of distortion. The camera need not be bulky; my ¼-plate camera is about the size of a postcard magazine camera. A "speed" colour camera for 3½-in. × 2½-in. plates that I am designing is about the size of a ¼-plate magazine.

The reader will have noticed that there is one inherent defect in all such cameras, and that is light-waste when the secondary image is absorbed by a complementary light-filter. He will therefore appreciate the gain and advantage of patent No. 110,089, of February, 1917, granted to Hesse-Ives Corporation for dichroic reflectors, reflecting green light and transmitting red. Eosine is one dye recommended, and is familiar to most readers as the old-fashioned red ink, which used to leave a green glint on the pen or where it dried in any thickness. A thin layer of gold is stated to behave similarly, but to be not so efficient. Further details and claims for this invention can be found in the "B.J." "Colour Photography" Supplement for March, 1918, or in the complete patent specification. It appears to be an invention of considerable value.

H. E. Rendall.

Screen-plate Pictures of "Old Masters."—We often hear (writes a correspondent) of screen-plate copies of "old masters" being too yellow or too green, or unsatisfactory and disappointing in other ways. This defect appears to be due to the discolouration of the varnish on the picture, varnish which has, for instance, turned Gainsborough's famous "Blue Boy" into a green one. Thus a screen-plate copy of the picture would show the clothes to be green instead of blue, the varnish appearing to be even more visible to the emulsion, than to the eye. The "Blue Boy" picture, the "Evening News" states, is to be cleaned and made perfect. "It is really quite natural that the picture should have a green tinge," said an expert to the paper's representative, "for if you look at varnish in a bottle it is yellow, and everyone knows that yellow and blue make green. As the varnish gets dirty it becomes more opaque and more yellow. There are probably several coats of varnish on the 'Blue Boy' which will have to come off, for no doubt it will be necessary to get down to the original. There is no fear that the 'Blue Boy' will be spoilt in the cleaning, for paint will not come off after about 80 years (the 'Blue Boy' was painted 150 years ago). A picture can be over-cleaned. A man who did not know his work might take off even the varnish the artist had put on to soften the colours, and they would appear too clean and crude."

Colour Photography.

CONTENTS.

INTENSIFYING AUTOCHROMES.

As a general rule most of the Autochrome colour transparencies made by amateurs are all the better for intensification. Many formulæ have been put forward for this, but most represent difficulties in making up or are uncertain in action. The uranium intensifier, though quite effective in adding density, tends to upset the balance of the colours. Pyro silver has often been recommended and is the formula put forward by the manufacturers, but I must say that in my hands it has not proved very satisfactory. Other workers pin their faith to the mercuric intensifier, but, after a careful trial of most, I prefer the chromium bleacher as introduced by the late C. Welborne Piper, which has several distinct advantages over the others. It is simple to use, its action is certain, and the degree of intensification is easily controlled, and, not least in importance to many, the formula contains no scheduled poison. A description of my own method of using the chromium intensifier for Autochrome plates, though not new, may be of value to others. Many workers assume that the chromium intensifier is not equal in its results to those given by the more complicated pyro-silver, but I can only say that, in my own hands, the results are decidedly better, and, provided ordinary care is taken, the process is absolutely safe and certain even when used by the inexperienced worker.

In the first place, a little discrimination is needed in deciding when an Autochrome needs intensification. If the plate, after being removed from the second developer, seems satisfactory in every way, except that it is thin and the colours have a weak and washed-out appearance due to over-exposure, the qualities of the picture may be made good by careful intensification. This must not be mistaken for the flat, heavy results of under-exposure and the plate intensified under the impression that the additional density gained will put the matter right. For these there is no real cure, though reduction sometimes has the effect of slight improvement. But, in my opinion, these are best thrown away and the exposure repeated, correcting the original error.

Prior to attempting intensification upon an over-exposed plate, the transparency should be put back in the developer for at least another five minutes in strong light in order to ensure that the picture is fully developed. If this is neglected after the final re-development, when the plate is afterwards put in the necessary fixing bath, the action of the hypo upon the reduced silver may leave practically nothing of the picture. It is a good plan in order to ensure that the second development is effective, if the plate is to be intensified, to give the plate a few minutes in a bath of fresh developer.

To proceed with intensification, the bleacher may be made up according to the formula published in The British Journal Almanac, which I quote:—

A.—Potass bichromate, 1 oz.; water, 20 ozs.

B.—Hydrochloric acid, pure, 1 oz. fl.; 1.160 sp. gr. to 10 ozs.

The most satisfactory bleaching bath for Autochrome work is made up of 4 ozs. of A, 3 drachms of B, with 16 ozs. of water, or the tabloid preparation issued by Messrs. Burroughs Wellcome & Co., may be employed. The latter is very convenient, as the process is not one employed very frequently.

The transparency should be taken from the second developer and well washed in order to get the developer out of the film. This, with the thin Autochrome film, takes only a few minutes, when the plate is ready to be placed in the chromium bleacher. The action of this is rapid, half a minute being sufficient to bleach the film thoroughly, after which the plate should be held under a gentle stream of water from a tap for two or three minutes or until the film is fairly free from the yellow stain.

Re-development may then be proceeded with. The old developing solution should not be used, for I have found that there is a tendency for its action to be uneven, and particularly if it has been partially exhausted or discoloured by previous use. Moreover, its action is slow, and with the extreme delicacy of the Autochrome film anything that tends to prolong immersion in any of the solutions is to be avoided. My own preference is for Rytol, though amidol is entirely satisfactory and perhaps advisable if a second application of the intensifier is necessary, though any good non-staining developer will give good results.

If at the end of a couple of minutes in the developer the plate is examined it will probably be found considerably improved in colour rendering. It may, however, be thought that it is still far from perfect, and in this case the process may be repeated even to the extent of five or six times, provided the film does not show signs of leaving the plate or of blistering. Before the plate is bleached again the developer should be thoroughly washed out, for if this is not done there is a tendency for the action of the intensifier to be uneven, or stains may result. I have often intensified a weak over-exposed Autochrome several times and succeeded in the end in producing a passable transparency. Care should be taken not to hurry development by taking the plate out of the solution too soon, and if the solution is a non-staining one the process may be allowed to continue for several minutes, which ensures the image being fully developed out.

It sometimes happens that, after repeated intensification, the whites of an Autochrome plate may become stained and the

colours somewhat dull and brownish. If this happens the plate may be cleared by immersing it in a non-acid permanganate solution. MM. Lumière recommend the following formula :—

Potass permanganate, 15 grs. ; water 35 ozs.

Care must be taken not to mistake this for the reversing solution. If the Autochrome has become too heavy in character, the colours appearing clogged up and thus indicating that the intensification has been too great, it may be reduced by immersing it in the acid permanganate reversing solution used after the first development. This must be diluted to about thirty times its usual strength, or to a pale pink colour. The action of this reducer is rapid, and the plate should not be left in it for more than half a minute. A very short period of immersion in this bath will be found to clear the image very considerably

The next step is fixation. MM. Lumière say that fixing is indispensable when an Autochrome has been intensified. This probably applies more to the silver intensifier, which forms a fresh silver compound, but a fixing bath, if not absolutely essential for the chromium method, does no harm provided the plate has had a full second development in full light. I give my own Autochromes about three minutes in an ordinary acid fixing bath.

All that then remains is to give the plate a brief wash, say, for about five minutes in a gentle stream of running water, this being sufficient to remove the hypo from the film, after which the plate may be set up to dry in the usual way.

The foregoing, I think, deals fairly exhaustively with the advantages derived from the use of the chromium bleacher in Autochrome work. One other point I may add. All intensification should be done when the plate is wet, as an Autochrome that has once been dried, when re-wetted, tends to produce a crop of the green spots that were the bugbear of the photographer in the early days. Also, quite apart from this, the chances are the film may frill or entirely leave the glass. The worker should make up his mind as to the further treatment of the plate while it is still in the second developer, and the work should be at once proceeded with, thus avoiding re-wetting.

It should be the aim of the colour photographer to select his subject and so time his exposure that intensification or reduction will not be needed. There is a danger that the quality of the work may suffer through the photographer becoming careless as to his exposures, thinking that after treatment will put matters right. It may or it may not, though my own belief is that nothing can equal for beauty or brilliancy of colour an Autochrome that has been so exposed that no further treatment is needed beyond the second development. However successful intensification methods may be, they should be the exception and not the rule.

ROBERT M. FANSTONE.

THE CASIERI PROCESS OF COLOUR CINEMATOGRAPHY.

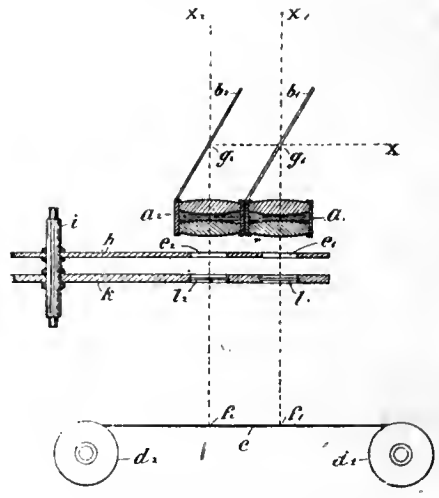
ACCORDING to a patent applied for in Italy in 1918 and now published as a British specification, the inventor, Giovanni Casieri, proposes to obtain cinematograph pictures in natural colours by a process of additive projection according to which pictures are taken in pairs alternately through two pairs of filters, and each pair taken simultaneously appear to have been taken from practically the same point of view.

One arrangement of the optical parts for carrying out the novel process is shown diagrammatically in the drawing, which is a horizontal section taken on a plane passing through the axes of the lenses, through the axes of the spindle of the shutter and through the colour filters.

As shown in the drawing, the lenses a_1, a_2, are mounted with their axes parallel and two glass plates b_1, b_2, are placed in front of them and parallel to one another and inclined at an angle of 45 deg. to the axes of the lenses. Both plates have parallel plane faces, the first of them being partly transparent and partly reflecting and the second totally reflecting. The film c advances in a plane at right angles to that containing the axes of the lenses, while it is drawn from the spool d^1 and wound up on the receiving spool d^2. After each exposure, the film is advanced by an amount equal to twice the distance between the centres of adjacent pictures if every image is of the size of a whole picture, or by an amount corresponding to a single step, if every monochromatic image is half that size.

In order to conform with the size of the films which are generally on the market, it is convenient to place the axes of the objectives at a distance apart of 18 millimetres.

By the arrangement adopted any luminous point x gives two images f^1, f^2, on the film, the first image f^1 being produced by the



partial reflection of the pencil meeting the plate b^1, and the second image f^2 being produced by the total reflection of the residual part of the pencil, passed through the first glass, and reflected by the reflecting surface b^2.

The total effect produced is the same as if there were two luminous points x^1 and x^2 in such a position that

$$x^2g^2 = g^2x, \text{ and } x^1g^1 = g^1x,$$

that is to say, as if the optical axes of both lenses were coincident with the line g^1g^2 and their optical centres were at a distance apart equal to $g^1g^2 = 18$ millimetres, which practically means that both centres are at the same distance from the luminous point, x.

It is obvious that the inclination of the reflecting surfaces at 45 deg. has been chosen only by way of example and as that inclination is the most convenient in practice, but the inclination of the reflecting plates to the axes of the lenses may be any other.

Two complementary light-filters are combined with the two objectives for the selection of the colours so that two complementary images are obtained both lying in the same plane, the plane of the film, and turned towards the same direction, the images being taken simultaneously and practically equivalent to two images obtained from a single point of view.

If the above arrangement were extended to a three-colour process, it would complicate the apparatus considerably, and in practice several difficulties would be encountered. Firstly, if it is desired not to diminish the size of the images, it is necessary to increase excessively the speed of movement of the film between two successive exposures, which would subject the film to considerable mechanical stresses liable to cause the film to break.

On the other hand, as the amount of light which is supplied to every image during the exposure cannot be increased according to the will of the operator, and would thus be reduced, in many cases the ordinary lighting of the subject would prove insufficient for good reproduction.

These difficulties are now all overcome, and the same effects which are usually obtained with three lenses are obtained by means of two lenses only, by substituting two movable pairs of complementary filters for the lenses, which pairs work alternately for taking the pictures as well as for projecting them.

Assume, for instance, that the apparatus comprises two pairs of screens, one of which is red and green and the other orange and blue, and that each pair is brought into operation eight times in a second. On the whole eight images for every colour will be obtained, that is to say thirty-two images, or eight series of pictures in four colours.

For projection, conversely, the images of every pair obtained on

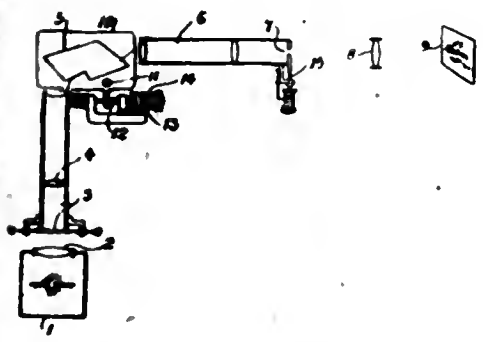
the negative by means of the two lenses and two complementary filters are projected simultaneously, by interposing in front of the positives filters of the same colours which had been used in obtaining the negatives, so that the two pairs of screens are alternately used. In a second, sixteen pairs of pictures in complementary colours will be thus projected on the screen, two by two simultaneously, so that, for instance, if during the first time in which the shutter is open, a pair of images is projected through the blue and orange filters, during the next time, the pair of images is projected through the red and green screens.

The filters in the reproducing as well as in the projecting apparatus are preferably mounted on the same spindle as the shutter, as is shown, by way of example, in the drawing, where *h* is the disc of the shutter and *k* the disc with the filters 1_1, 1_2, both discs being mounted on the same spindle.

SPECTRUM ILLUMINATION IN COLOUR-SENSATION NEGATIVE MAKING.

A RECENT patent specification, No. 166,028, of Adrian Bernard Klein, claims as a novelty the making of colour-sensation negatives by suitable spectral illumination of the subject instead of by the use of light-filters. The patentee deliberately claims the employment for this purpose of regions of spectrum illumination without overlap, and, in fact, alludes to the overlap in absorption of dye filters as an obstacle to satisfactory three-colour work. Nevertheless, it may be of interest to quote that part of the specification which describes the optical arrangement for producing illumination corresponding with any desired part of the spectrum.

The light from an arc lamp or other source 1 is passed through a condensing lens 2 and focussed upon an adjustable slit 3. Thence the light passes through a collimator 4 and through a constant deviation or dispersion prism 5. The light is dispersed by the prism into a spectrum which is then passed through a further collimator 6. After passing through this collimator the spectrum falls upon a surface which includes a second slit 7 which is adjustable in such a manner as to permit the passage of light from any desired portion of the spectrum. This transmitted light is then passed through a condensing lens 8 and thrown upon the object 9 to be photographed.



The prism 5 is preferably mounted on a platform 10 rotatable at a suitable point about a pivot 11 so that any desired portion of the spectrum can be brought into alignment with the second collimator 6 and a fixed edge of the slit 7 by rotation of a micrometer screw 12 the movement of which can be determined by a fixed pointer 13 reading on a drum scale 14 graduated in a suitable manner, as for instance in wave lengths, and the slit 7 preferably comprises a movable shutter operated by a micrometer screw 15 the movement of which can also be determined by means of a scale graduated in a suitable manner. Thus by suitably adjusting the two micrometer screws 12 and 15 the light thrown upon the object may be selected from any desired portion of the spectrum.

The prism 5 is surrounded by a suitable fixed casing (not indicated in the drawings) having apertures registering with the adjacent ends of the two collimators.

Instead of providing a rotatable prism both edges of the slit 7 may be made adjustable, suitable scales or indicators being provided for determining the positions to which they must be adjusted to give the desired divisions of the spectrum. A constant deviation prism is preferably employed owing to the fact that it simplifies the scales employed for the micrometer screws, but any other prism may be employed if desired.

CLERK MAXWELL'S THEORY AND HIS PRACTICE.

PROBABLY everyone, even those not specifically interested in colour photography, knows that to Clerk Maxwell we are indebted for the first suggestion as to the possibility of reproducing the colours of nature by photography. And it would seem as though he had argued this out as a proof of the correctness of his colour mixture theory. It is unnecessary to recapitulate this, as it has been pretty well threshed out in the pages of the "B.J."[1]

But apparently no one has taken the trouble to find out whether there existed any record of the photographic side of the work carried out to obtain the results which were shown at the time of his lecture, and it has been generally assumed that the negatives were made and the positives projected by red, green and blue-violet light.

Possibly one reason for this neglect is that it was practically impossible to carry the process into effect till the discovery of orthochromatism by H. W. Vogel in 1873, and then the main features of the argument were only remembered, and, further, no one but the dry-as-dust historian cares one iota as to the actual data. Even Howard Farmer[2], who seems to have paid more attention to the operative details than anyone else, accepted the familiar triad of red, green and blue-violet.

Having occasion, for another purpose, to refer to the original publications of Clerk Maxwell's work, I found fairly complete details, and was considerably surprised, as actually not only was the negative process a four-colour one, but the positives were projected by four colours also.

The work was carried out by Thos. Sutton, who was the Editor of "Photographic Notes," and also at the time, I believe, lecturer on photography at King's College. He gave an account of the work in his paper, and this was reprinted in the "Photographic News,"[3] and I venture to think that it is of sufficient interest historically to be rescued from oblivion. Sutton says: "A bow made of ribbon, striped with various colours, was pinned upon a background of black velvet, and copied by photography by means of a portrait lens of full aperture, having various coloured fluids placed immediately in front of it, and through which the light from the object had to pass before it reached the lens. The experiments were made out of doors, in a good light, and the results were as follows:—1st. A plate-glass bath, containing the ammoniacal sulphate of copper, which chemists use for the blue solution in the bottles in their windows, was first placed immediately in front of the lens. With an exposure of six seconds a perfect negative was obtained. This exposure was about double that required when the coloured solution was removed. 2nd. A similar bath was used, containing a green solution of chloride of copper. With an exposure of twelve minutes not the slightest trace of a negative was obtained, although the image was clearly visible upon the ground-glass. It was, therefore, found advisable to dilute the solution considerably; and, by doing this, and by making the green tinge of the water *very* much paler, a tolerable negative was eventually obtained in twelve minutes. 3rd. A sheet of lemon-coloured glass was next placed in front of the lens, and a good negative obtained with an exposure of two minutes. 4th. A plate-glass bath, similar to the others, and containing a strong red solution of sulphocyanide of iron, was next used, and a good negative obtained with an exposure of eight minutes. It is impossible to describe in words the exact shades of colour, or intensity of these solutions. The thickness of the fluid through which the light had to pass was about three-quarters of an inch. The collodion was simply iodised, the bath neutral, and the developer pyrogallic acid. The chemicals were in a highly-sensitive state and good working order, producing clean and dense negatives, free from stains and streaks in all cases."

"The negatives taken in the manner described were printed by the tannin process upon glass, and exhibited as trans-

parencies. The picture taken through the red medium was at the lecture illuminated by red light, that through the blue medium by blue light, that through the yellow medium by yellow light, and that through the green medium by green light, and when these different-coloured images were superposed upon the screen, a sort of photograph of the striped ribbon was produced in the natural colours."

As already stated, access to the original has not been possible, but I hope that someone will take the trouble to look up the subject to determine whether any further notes appeared. Speculation as to this departure from the theoretical procedure is possible, but whether it would be profitable is another question. It is, however, of interest to note that the exposure through the red filter was less than that for the green, even although the latter was much reduced in strength, which, one might argue, proves that the sensitive salt, the iodide, was more sensitive to red than to green. Possibly the yellow filter was used to supplement the action of the green.

E. J. WALL, F.R.P.S.

A NEW THREE-COLOUR CAMERA.

(A Note in "Penrose's Annual," 1922.)

THERE have been many attempts to devise a camera for taking the three exposures for three-colour records with a single lens, either simultaneously or in quick succession. A camera designed and patented by Mr. A. Roland Trist falls in the latter category, and it seems to carry out this method of working in a most successful manner.

In external appearance and size it resembles one of the now old-fashioned, box-type magazine hand-cameras, in which the plates are changed internally. On opening the front of the box body it is seen that the lens is fitted with a rotating disc of ebonite with four openings; three of these openings contain the red, blue and green filters, the fourth is blank. Each of the openings containing the colour filters is fitted with an iris diaphragm, which can be independently operated, so as to give an aperture proportional to the exposure factor for each colour. An engraved scale is fixed to the camera indicating the apertures for each filter for a given plate-maker's factor. The camera is fitted with one of the finest lenses for colour work, namely, the Goerz Dagor Apochromatic, working at an aperture of *f*/6.8, fitted with a compound shutter.

All the operator has to do is to place panchromatic plates in the metal sheaths and put them in the magazine holder, then set up the camera, centre the subject in the direct vision finder (there being no focussing screen), and measure distance of subject to lens, racking out the lens until the number of feet is indicated on the scale. The camera is then set by revolving the colour filter holder, so that the blue comes into position for the first exposure. The shutter is set to the exposure determined by a reliable actinometer, and at the side of the camera is a small lever, which, when pressed, always sets the camera to the right position for starting; otherwise the plate may drop before the shutter opens, instead of *vice versa*. Everything being now ready, the operator presses the Antinous release twice; the first push opens the shutter and shuts it, the second drops the exposed plate to the bottom of the magazine, at the same time revolving the colour filter holder to the next colour. The time between the exposures is extremely short, averaging about two seconds, which allows very little time for any change in the light between exposures affecting the results. The camera is entirely automatic, and any photographer can work it without practice, being as simple as using a Kodak. It is quite easy to obtain three negatives of uniform density and sharpness, so that the difficult part of three-colour work is accomplished.

The writer has tested this camera, and found it to be the most perfect yet produced; the negatives were sharp, clear and the density absolutely equal in all three, the register also being perfect.

The inventor has set out with the idea of bringing colour work within the scope of the amateur photographer. The camera so far has only been made in quarter-plate and 5 x 4 size, but there is no reason why it should not be made in larger sizes for studio work, or for process reproduction, and it may become a valuable aid in practical work.

Naturally for such purposes the camera will have to be provided with a focussing screen, and set up on a stand, but there should be no difficulty in doing this; further it would be necessary to make a scale of factors for electric illumination.

DYEING SENSITIVE FILMS FOR RELIEF PRINTS.

To the Editors.

Gentlemen,—In the "Colour Photography" Supplement of September 2 (p. 36), Mr. Wall appears to discredit my claim to the first use of a non-actinic dye in sensitive films in the production of photo-gelatine relief prints, for the purpose of obtaining tenuous reliefs. He also says (page 34) that the height of the relief is of not the slightest importance for superimposed films. Mr. Wall mentions Ducos Du Hauron, Lumière, Sanger-Shepherd and Bartlett, and O. Pfenninger as employing this method, but overlooks the fact that it was first disclosed and patented by me (U.S. Patent 980,962, January 10, 1911—application dated April 28, 1910), and afterwards adopted by the parties named without credit to me. I was also clearly the first to dye a gelatine bromide film with non-actinic dye as one step in the production of tenuous relief prints through the medium of a developed silver image, and the claims in my patent are perfectly valid. The tenuous reliefs permitted the production of imbibition prints on hard gelatine paper, such as Velox backing paper, with exquisitely sharp definition, which was not possible with methods previously disclosed. They also permitted of quick dyeing in my patented standardised dye baths (U.S. Pat. 1,121,187, December 15, 1914, pp. 3, 4), with which the depth of colour can be perfectly controlled, being independent of the time of immersion after once dyeing evenly through to the back, and by means of which any desired number of exact duplicates could be and were produced to order in Hicrome and imbibition process prints.

The bleach-hardening solution given in my patent cited by Mr. Wall was improved upon before the patent was issued, eliminating the features criticised by Mr. Wall.

The production of extremely tenuous relief prints was only one element of a completely worked out and perfect system having other notable original features. I am not responsible for the fact that the method is not well known and extensively used, as it should be.—Very truly yours,

F. E. IVES

INVENTIONS IN COLOUR CAMERAS.

To the Editors.

Gentlemen,—In the interest of correct historical record permit me to point out that the type of camera credited to White and to Butler in Mr. Rendall's article on page 43 of the "Colour Photography" Supplement (November 4) was originally patented by me in 1894 (U.S. Pat. 531,940); also that the bending of the transparent reflector to secure perfect registration, which is credited to Hamburger, was originally patented by me in 1898 (U.S. Patent issued April 4, 1899, No. 622,480), and the dichroic reflector is also my own invention.

I think Mr. Rendall would find my "Tripak" system, patented in 1909 (U.S. Patent issued January 10, 1911), far more convenient and satisfactory than the cameras which he mentions. Unfortunately, there has not been sufficient practical interest in these inventions to justify manufacture in this country.—Very truly yours,

F. E IVES.
